1.1 INTRODUCTION*

Antennas are key components of any wireless communication system.^{1,2} They are the devices that allow for the transfer of a signal (in a wired system) to waves that, in turn, propagate through space and can be received by another antenna. The receiving antenna is responsible for the reciprocal process, i.e., that of turning an electromagnetic wave into a signal or voltage at its terminals that can subsequently be processed by the receiver. The receiving and transmitting functionalities of the antenna structure itself are fully characterized by Maxwell's equations and are fairly well understood.³ The *dipole antenna* (a straight wire, fed at the center by a two-wire transmission line) was the first antenna ever used and is also one of the best understood.^{1,2} For effective reception and transmission, it must be approximately $\lambda/2$ long (λ = wavelength) at the frequency of operation (or multiples of this length). Thus, it must be fairly long (or high) when used at low frequencies ($\lambda = 1$ m at 300 MHz), and even at higher frequencies (UHF and greater), its protruding nature makes it quite undesirable. Further, its low gain (2.15 dB), lack of directionality, and extremely narrow bandwidth make it even less attractive. Not surprisingly, the Yagi-Uda antenna (typically seen on the roof of most houses for television reception) was considered a breakthrough in antenna technology when introduced in the early 1920s because of its much higher gain of 8–14 dB. Log-periodic wire antennas introduced in the late 1950s and 1960s and wire spirals allowed for both gain and bandwidth increases. On the other hand, even today high gain antennas rely on large reflectors (dish antennas) and waveguide arrays (used for many radar systems).

Until the late 1970s, antenna design was based primarily on practical approaches using off-the-shelf antennas such as various wire geometries (dipoles, Yagi-Uda, log-periodics, spirals), horns, reflectors, and slots/apertures as well as arrays of some of these. The antenna engineer could choose or modify one of them based on design requirements that characterize antennas, such as gain, input impedance, bandwidth, pattern beamwidth, and sidelobe levels (see References 4 and 5 for a description of these quantities). Antenna development required extensive testing and experimentation and was, therefore, funded primarily by governments. However, in recent years, dramatic growth in computing speed and development of effective computational techniques for realistic antenna geometries has allowed for low-cost virtual antenna design. Undoubtedly, the explosive growth of wireless communications and microwave sensors, microwave imaging needs, and radars has been the catalyst for introducing a multitude of new antenna designs over the past decade and an insatiable desire for using modern computational techniques for low-cost designs. Requirements for

* Heinrich R. Hertz was the first to demonstrate the generation of radio waves at UHF using a gap dipole in 1885–1886 at Karlsruhe University (Germany). Hertz was able to detect radio waves 20 m away using a high-voltage electrical spark discharge to excite the dipole gap. From recorded conversations, Hertz did not seem to understand the impact of his experiments, but instead did it as a validation of the newly developed Maxwell's equations. Within ten years, Tesla at the Franklin Institute in the U.S., Marconi in Bologna, Italy, Popov in Russia, and Bose in India, demonstrated *wireless telegraphy*. In 1892, Tesla delivered a widely distributed presentation at the IRE of London about "transmitting intelligence without wires," and in 1895, he transmitted signals detected 50 miles (80 km) away. Concurrently, in 1894 Bose used wireless signals to ring a bell in Calcutta, and Popov presented his radio receiver to the Russian Physical & Chemical Society on May 7, 1895. Marconi is certainly considered the key individual for his contributions to the commercialization of radio waves, and he received the Nobel prize for his work in 1909. Nevertheless, Marconi's widely advertised first radio wave transmission experiment was in 1895, and his British patent application in 1897 was preceded by that of Tesla. A culmination of Marconi's experiments was the December 12, 1901, trans-Atlantic radio wave transmission of the Morse code for the letter S. The success of this experiment is often disputed, possibly due to strong atmospheric noise during the time of the experiment, but by the 1920s the U.S. had hundreds of radio stations, and in 1922, the BBC began transmitting in England. Subsequent development of radio detectors, vacuum tubes, and the tiny transistor in 1947 played a critical role in the practical everyday use of radio waves for communication and wireless transmission of information.

conformal antennas (non-protruding) for airborne systems, increased bandwidth requirements, and multifunctionality have led to heavy exploitation of printed (patch) or other slot-type antennas⁴ and the use of powerful computational tools (commercial and noncommercial) for designing such antennas.

Needless to say, the commercial mobile communications industry has been the catalyst for the recent explosive growth in antenna design needs. Certainly, the past decade has seen an extensive use of antennas by the public for cellular, GPS, satellite, wireless LAN for computers (WiFi), Bluetooth technology, Radio Frequency ID (RFID) devices, WiMAX, and so on. However, future needs will be even greater when a multitude of antennas are integrated into say automobiles for all sorts of communication needs and into a variety of portable devices and sensors for monitoring and information gathering. Certainly, future RFID devices will most likely replace the bar codes on all products while concurrently allowing for instantaneous inventorying. For military applications, there is an increasing need for small and conformal multifunctional antennas that can satisfy a plethora of communications needs using as little space as possible.

In this first chapter of the handbook, we provide a summary of antenna fundamentals and introduce antenna parameters typically used for characterizing antenna properties often employed to evaluate the entire radio system. We start with the radiation of an ideal (Hertzian) or infinitesimal dipole and proceed to the resonant $\lambda/2$ dipole, antenna arrays, and mobile communication concepts.

1.2 HUYGENS' AND EQUIVALENCE PRINCIPLES

The electromagnetic behavior and thus the functioning of antennas is governed by Maxwell's equations,³ which must be solved for a particular antenna and a given excitation. Typically, exact solutions of Maxwell's equations are not available and thus numerical modeling is often used to compute approximate solutions for practical configurations. A formal simplification of electromagnetic antenna problems can be achieved by employing the equivalence principle.³ If interest is restricted to the field solution in a limited region of space, the antenna configuration can be replaced by the equivalent electromagnetic sources located on the surface of a volume enclosing the antenna configuration (see Figure 1-1). Because the antenna materials are no longer there, these sources are usually radiating in a homogeneous solution space (such as free-space), and the corresponding fields can thus be calculated by evaluating the radiation integrals.

The equivalent sources are not uniquely defined, and there are many different ways of constructing them. In general, the equivalent sources are a composition of electric and magnetic surface current densities representing the excitation terms in Maxwell's equations. A straightforward way of constructing equivalent sources is provided by Huygens' principle.³ Huygens' principle states that the field solution in a region V is completely determined by the tangential fields over the surface S enclosing V . The corresponding electric and magnetic equivalent surface current densities are given by

Electric current density:

$$\mathbf{J} = \hat{n} \times \mathbf{H} \quad (1-1)$$

Magnetic current density:

$$\mathbf{M} = -\hat{n} \times \mathbf{E} \quad (1-2)$$

FIGURE 1-1 Replacement of an antenna by equivalent electric and magnetic surface current densities

where both \mathbf{J} and \mathbf{H} are expressed in amperes per meter (A/m) and \mathbf{M} and \mathbf{E} are expressed in volts per meter (V/m). For the problem of a radiating antenna, as illustrated in Figure 1-1, the outer boundary of V is assumed to be located at infinity, where the fields radiated by the corresponding equivalent sources can be neglected. As shown in the figure, the antenna can be replaced by equivalent sources on an arbitrary surface S enclosing it. As already mentioned, these equivalent sources reproduce the radiated fields of the antenna, and they can be assumed as radiating in homogeneous space. For a particular antenna configuration, the exact determination of \mathbf{J} and \mathbf{M} requires knowledge of the true field distribution on S . However, for many practical antennas, an approximate determination of \mathbf{J} and \mathbf{M} is possible. For instance, placing S to coincide with a metallic section of the antenna structure causes \mathbf{M} to vanish on these portions of S .

The radiated fields from any antenna can be obtained by integrating the field contributions of the equivalent electric and magnetic current densities using the well-known radiation integral:³

$$\mathbf{E} = -j\omega\mu_0 \oint\oint_S \left[\mathbf{J}(\mathbf{r}') \frac{e^{-jk_0|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} + \frac{1}{k_0^2} (\nabla' \cdot \mathbf{J}(\mathbf{r}')) \nabla \frac{e^{-jk_0|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \right] ds' \\ + \oint\oint_S \mathbf{M}(\mathbf{r}') \times \nabla \frac{e^{-jk_0|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} ds'$$

which for the far-field ($r \rightarrow \infty$) reduces to (see Figure 1-1)

$$\mathbf{E} = -j\omega\mu_0 \frac{e^{-jk_0r}}{4\pi r} \oint\oint_S \left[(\bar{\mathbf{I}} - \hat{\mathbf{r}}\hat{\mathbf{r}}) \cdot \mathbf{J}(\mathbf{r}') - \sqrt{\frac{\epsilon_0}{\mu_0}} \hat{\mathbf{r}} \times \mathbf{M}(\mathbf{r}') \right] e^{jk_0\hat{\mathbf{r}} \cdot \mathbf{r}'} ds'$$

where

$\bar{\mathbf{I}}$ = unit dyad

\mathbf{r} = defines location of observation point (see Figure 1-1)

r = distance (in m) to observation point

\mathbf{r}' = defines location of the integrated surface current densities

$\hat{\mathbf{r}}$ = unit vector in radial direction

ϵ_0 = free-space permittivity

μ_0 = free-space permeability

$$Z_0 = \sqrt{\frac{\mu_0}{\epsilon_0}} = \text{free-space impedance}$$

$$k_0 Z_0 = \omega \mu_0$$

$$k_0 = \beta = 2\pi / \lambda$$

$$\lambda = \text{wavelength (in meters, m)}$$

$$j = \sqrt{-1}$$

$$E \text{ is given in volts per meter (V/m)}$$

$$H \text{ is given in amperes per meter (A/m)}$$

For the ideal (delta) or infinitesimal electric (Hertzian) or magnetic (Fitzgerald) dipole sources, the radiation integrals are eliminated and the fields can be given in closed forms. The resulting field expressions can then be used to extract and study the usual antenna parameters.

1.3 HERTZIAN AND FITZGERALD ELEMENTARY RADIATORS

Considering the infinitesimal electric dipole $\mathbf{J} = \hat{z} Idz \delta(z)$, as illustrated in Figure 1-2, the resulting rms (root mean square) electric and magnetic field components are given by

$$\begin{aligned} E_r &= k_0^2 \sqrt{\frac{\mu_0}{\epsilon_0}} \frac{Idz}{2\pi} \left[\frac{1}{(k_0 r)^2} - \frac{j}{(k_0 r)^3} \right] \cos\theta e^{-jk_0 r}, \\ E_\theta &= jk_0^2 \sqrt{\frac{\mu_0}{\epsilon_0}} \frac{Idz}{4\pi} \left[\frac{1}{k_0 r} - \frac{j}{(k_0 r)^2} - \frac{1}{(k_0 r)^3} \right] \sin\theta e^{-jk_0 r}, \\ H_\phi &= jk_0^2 \frac{Idz}{4\pi} \left[\frac{1}{k_0 r} - \frac{j}{(k_0 r)^2} \right] \sin\theta e^{jk_0 r}, \\ F &= H = H = 0 \end{aligned} \quad (1-3)$$

where

Idz = moment of the differential current element
(I is given in rms amperes, and dz is given in meters)

FIGURE 1-2 Coordinate system for an electric dipole

A time factor of $e^{j\omega t}$ has been suppressed since a sinusoidally time-varying current excitation of constant frequency is assumed. These are the exact fields, but antenna parameter evaluation is usually carried out using simplified far-fields, i.e., when r is much greater than the wavelength λ . Under these conditions, terms of order $1/r^2$ and greater are neglected to obtain

$$\begin{aligned} E_\theta &= jk_0 \sqrt{\frac{\mu_0}{\epsilon_0}} \frac{Idz}{4\pi} \sin\theta \frac{e^{-jk_0 r}}{r} = \sqrt{\frac{\mu_0}{\epsilon_0}} H_\phi, \\ H_\phi &= jk_0 \frac{Idz}{4\pi} \sin\theta \frac{e^{-jk_0 r}}{r} = \sqrt{\frac{\epsilon_0}{\mu_0}} E_\theta. \end{aligned} \quad (1-4)$$

The complex Poynting vector \mathbf{S}^3 in the far-field is given by

$$\mathbf{S} = \mathbf{E} \times \mathbf{H}^* = k_0^2 \sqrt{\frac{\mu_0}{\epsilon_0}} \frac{Idz}{16\pi^2} \frac{\sin^2\theta}{r^2} \hat{r} \quad (1-5)$$

showing that it is a purely real quantity and indicating that power transport is in the r direction (away from the elementary current) without any reactive energy. Also, it is seen that the radiated power density (power flow per unit area) for any $r = \text{const.}$ depends on $\sin^2\theta$ (independent of ϕ). This is referred to as the radiation pattern plotted in dB. For an elementary (ideal or infinitesimal) magnetic dipole $\mathbf{M} = \hat{z} I_m dz \delta(z)$, the radiated fields can be found by duality³ (replacing E by H , H by $-E$, and I by I_m).

1.4 FAR-FIELD ANTENNA PROPERTIES, POWER TRANSFER, AND RECIPROCITY

Because antenna radiation can be represented by radiation integrals over equivalent current sources, as considered in the previous paragraph, no reactive field components will be found in the far-field of any antenna. Further, far-field antenna characterization can be performed by considering power flow under the constraint of energy conservation. However, the distance from an antenna to its far-field depends on the antenna, and it is commonly accepted that the far-field region starts after the distance

$$R = r = \frac{2D^2}{\lambda} \quad (1-6)$$

where D is the largest dimension of the antenna. This is due to the varying propagation distances of field contributions from different parts of the antenna to an observation point P , as illustrated in Figure 1-3. In the far-field, every antenna is considered a point source, and the far-field criterion in Eq. 1-6 is derived under the assumption that the phase errors due to the varying propagation distances are less than $\pi/8$.

Consider an antenna located at the origin of a spherical coordinate system, as illustrated for the electric current element in Figure 1-2. Assume that the *antenna is transmitting* and let

- P_t = power accepted by the antenna (in Watts)

FIGURE 1-3 Schematic representation of an antenna aperture showing the observation point P and the distances to the observation point from two points on the antenna

- P_{rad} = power radiated by the antenna (in Watts)
- η = radiation efficiency (unitless)

These quantities are related by

$$\eta = \frac{P_{\text{rad}}}{P_t} \quad (1-7)$$

Let

- $S_i(\theta, \phi)$ = power density (in Watts/square meter, W/m^2)

and remark that $S_i(\theta, \phi)$ is independent of the distance from the antenna r , a characteristic of the far-field region. The total radiated power can be obtained by integrating the power density over a surface enclosing the antenna. Such a surface can be of any shape and can be as close to the antenna as desired. However, for simplicity, it is convenient to choose the surface to be a sphere, giving

$$P_{\text{rad}} = \int_0^{2\pi} \int_0^\pi S_i(\theta, \phi) r^2 \sin\theta \, d\theta \, d\phi \quad (1-8)$$

with the average power density being

$$P_{\text{avg}} = \frac{P_{\text{rad}}}{4\pi r^2} \quad (1-9)$$

Now, let

- $D_i(\theta, \phi)$ = directivity (unitless)

Directivity is a measure of the antenna to concentrate radiated power in a particular direction, and it is related to power density as

$$D_i(\theta, \phi) = \frac{S_i(\theta, \phi)}{P_{\text{avg}}} = \frac{S_i(\theta, \phi)}{P_{\text{rad}} / (4\pi r^2)} \quad (1-10)$$

The directivity of an antenna is the ratio of the achieved power density in a particular direction to that of an isotropic antenna.

Let

$$G_i(\theta, \phi) = \text{gain (unitless)}$$

The gain of an antenna is related to the directivity and radiated power density via the relation

$$G_i(\theta, \phi) = \eta D_i(\theta, \phi) = \frac{\eta S_i(\theta, \phi)}{P_{\text{rad}} / (4\pi r^2)} \quad (1-11)$$

and from Eq. 1-7

$$G_i(\theta, \phi) = \frac{S_i(\theta, \phi)}{P_i / (4\pi r^2)} \quad (1-12)$$

If you have a lossless antenna (i.e., $\eta = 1$), the directivity and the gain will be identical.

Now consider a *receiving antenna* exposed to a power density radiated from some transmitting antenna. The ability of the antenna to receive energy is quantified through

- $A_{e,r}(\theta, \phi)$ = effective area (in square meters)

where the antenna's location is assumed to be at the origin of the coordinate system.

Under the assumption of reciprocity,⁵ the effective area of an antenna is related to the gain via the relation

$$A_{e,r}(\theta, \phi) = \frac{\lambda^2}{4\pi} G_r(\theta, \phi) \quad (1-13)$$

where λ = wavelength. Note that reciprocity holds only for lossless antennas. Also, Eq. 1-13 depends on wavelength and therefore on frequency. Under these circumstances, antenna characterization can be performed either for the transmitting or receiving case with behavior for the other being immediately known.

Suppressing the angular dependencies of the transmitting and receiving antennas in their local coordinate systems, the received power is equal to the product of the power density of the incident wave and the effective aperture of the receiving antenna. That is

$$P_r = S_i A_{e,r}$$

Substituting from Eq. 1-12 and Eq. 1-13 yields

$$P_r = \frac{G_i P_i}{4\pi r^2} \frac{\lambda^2 G_r}{4\pi}$$

or

$$P_r = \left(\frac{\lambda}{4\pi r} \right)^2 G_i G_r P_i \quad (1-14)$$

FIGURE 1-4 Antenna pattern in plane $\phi = \text{const}$

Note that G_t is the gain of the transmitting antenna in the direction of the receiving one and G_r is the gain of the receiving antenna in the direction of the transmitting one. A form of this equation was presented first by Friis⁶ and is usually called the *Friis transmission formula*.

The angular dependence of the radiating and receiving properties of an antenna in the far-field is often referred to as the *antenna radiation pattern*. Thus, a pattern is a normalized plot of the directivity, gain, or effective aperture as a function of angle and is often given in dB scale. Typically, the radiated normalized radiated power density or radiated field is plotted in dB (for the infinitesimal or ideal dipole, the power density $\sin^2 \theta$ is plotted in dB). A typical antenna pattern has a main lobe, sidelobes, minor lobes, a backlobe, and several nulls, as illustrated in Figure 1-4, in a $\phi = \text{const}$. plane. The half-power or 3 dB beamwidth of the main lobe (or main beam) is indicated in the drawing. If the pattern of an antenna is given in a plane parallel to the **E** field vector, the corresponding pattern is referred to as an **E** plane pattern. Alternatively, if the pattern cut is in a plane parallel to the **H** field polarization, it is called an **H** plane pattern.

There are many types of antenna radiation patterns, but the most common are

- Omnidirectional (azimuthal-plane)
- Pencil beam
- Fan beam
- Shaped beam

The *omnidirectional* pattern is most popular in communication and broadcast applications. The azimuthal pattern is circular, but the elevation pattern has some directivity to increase the gain in the horizontal direction. The term *pencil beam* is applied to a highly directive antenna pattern consisting of a major lobe contained within a cone of a small solid angle. Highly directive antenna patterns can be employed for point-to-point communication links and help reduce the required transmitter power. A *fan beam* is narrow in one direction and wide in the other. A *fan beam* is typically used in search or surveillance radars. *Shaped beam* patterns are adapted to the requirements of particular applications.

1.5 ANTENNAS AS ELECTROMAGNETIC CIRCUITS

A symbolic transition between a waveguide (transmission line) and an antenna is shown in Figure 1-5. In the case of a radiating antenna, a guided wave with amplitude a is traveling

toward the antenna and is more or less radiated into the surrounding medium. In the case of a receiving antenna, the received energy is transferred into a guided wave with amplitude b traveling down the waveguide away from the antenna. Consequently, from a circuit's viewpoint, the antenna can be considered as a one-port element provided only one guided mode exists at the port, as is normally the case; higher order modes can be considered as additional ports.

In the radiating mode, the one-port element is characterized by its complex reflection coefficient,

$$\Gamma = \frac{b}{a} \quad (1-15)$$

In the receiving mode, the received signal is converted into a traveling wave of amplitude b_0 . In general, the guided wave amplitude b at the antenna port is given by

$$b = \Gamma a + b_0 \quad (1-16)$$

If the antenna is a two-terminal circuit, equivalent network parameters are employed to describe the antenna behavior within the context of an electromagnetic circuit. Accordingly, the antenna may be replaced by equivalent circuit models such as those given in Figure 1-6, where the antenna is characterized by a) its input impedance Z and a source voltage V_0 or b) its input admittance Y and a source current I_0 . In the transmitting mode, V_0 or I_0 is zero, and V_{in} or I_{in} is the input voltage or current that drives the antenna. Part of the source power is dissipated in the loss resistance R_{loss} or loss conductance G_{loss} . The power associated with the radiation resistance R_{rad} or radiation conductance G_{rad} is responsible for the radiated wave that escapes from the antenna to the surrounding space. The quantities X and B refer to the equivalent reactance and susceptance of the antenna.

When the antenna is receiving, the terminals of the equivalent circuit are connected to a load (amplifier, speaker, etc.), and V_0 or I_0 are non-zero as dictated by the external wave that impinges on the antenna. Maximum transmission to the load occurs when the load impedance is the conjugate of the input antenna impedance. Some of the received energy usually remains within the radiation resistance or conductance and is re-radiated to contribute to the radar cross section (RCS) of the antenna. Mismatches between the load and the antenna input impedance can lead to higher or lower RCS. However, care must be exercised when

FIGURE 1-6 (a) Impedance (Thevenin equivalent) and (b) admittance (Norton equivalent) representations of an antenna

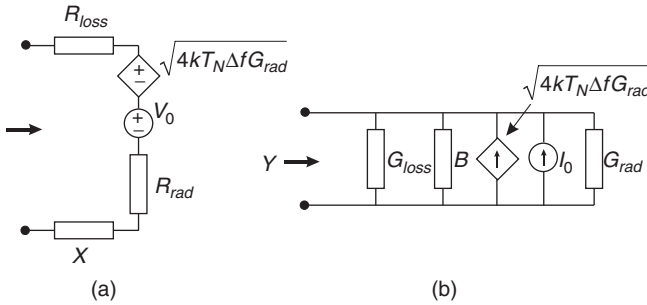

FIGURE 1-7 (a) Impedance (Thevenin equivalent) and (b) admittance (Norton equivalent) representations of an antenna including noise sources

the re-radiated energy is determined using equivalent circuit representations such as those in Figure 1-6. Reasonable results can only be expected if the employed equivalent circuit is an appropriate representation of the antenna's internal structure. Also, the equivalent circuits of one antenna can be different for radiation and reception.

Each antenna receives noise radiation related to the brightness temperature of its environment. Usually, the received noise power restricts the performance of an antenna and subsequent processing devices. However, in remote sensing or astronomy applications, the noise power can even be the intended signal. To formally account for the received noise power, the equivalent circuits in Figure 1-6 must be used with V_0 and I_0 representing sources dependent on the equivalent noise temperature T_N of the antenna. The dependent source voltages and source currents are given in Figure 1-7, where k is the Boltzmann constant and $BW = \Delta f$ is the receiver or antenna bandwidth. T_N is dependent on the radiation (or rather receiving) pattern and orientation of the antenna as well as the distribution of the brightness temperature in the environment of the antenna.[†]

Usually, antennas work at certain frequencies. The bandwidth

$$BW = f_U - f_L \quad (1-17)$$

is the operational frequency range of the antenna around some center frequency

$$f_0 = 1/2(f_U - f_L) \quad (1-18)$$

(e.g., the resonance frequency of the antenna). In this equation, the upper operational frequency limit is f_U , and the lower operational frequency is f_L . Often, the bandwidth is quoted with respect to f_0 percent, and in that case, it is given by

$$BW = (f_U - f_L)/f_0 \text{ } 100\% \quad (1-19)$$

From a circuit point of view, the matching of an antenna to the generator is very important. Therefore, bandwidth definitions with respect to the reflection coefficients or input impedances are common, for example,

$$|\Gamma| = |(Z_{in} - Z_0)/(Z_{in} + Z_0)| < 0.5 \quad (1-20)$$

[†] Further noise considerations with respect to antennas can be found in the literature.^{1,2,11,16}

Typically, the voltage standing wave ratio (VSWR)

$$\text{VSWR} = (|\Gamma| + 1)/(|\Gamma| - 1) < 2 \quad (1-21)$$

is used to define the operational bandwidth. Bandwidth definitions with respect to gain or other antenna pattern characteristics (for example, $G_0/G_{0,\max} < 0.5$) can be used to characterize the antenna radiating and receiving properties.

1.6 POLARIZATION

Polarization is a property of a single-frequency electromagnetic wave; it describes the shape and orientation of the locus of the extremity of the field vectors as a function of time.^{7,8} In antenna engineering, the polarization properties of plane waves or waves that can be considered to be planar over the local region of observation are of interest. For plane waves, it is sufficient to specify the polarization properties of the electric field vector since the magnetic field vector is simply related to the electric field vector. The plane containing the electric and magnetic fields is called the *plane of polarization* and is orthogonal to the direction of propagation. Generally, the tip of the electric field vector moves along an elliptical path in the plane of polarization. The polarization of the wave is specified by the shape and orientation of the ellipse and the direction in which the electric field vector traverses the ellipse.

The shape of the ellipse is specified by its *axial ratio*—the ratio of the major axis to the minor axis. Its orientation is specified by the *tilt angle*—the angle between the major axis and a reference direction when viewed looking in the direction of propagation. The direction in which the electric field vector traverses the ellipse is the *sense of polarization*—right-handed or left-handed when viewed looking in the direction of propagation.

The polarization of an antenna in a specific direction is defined to be the polarization of the far-field radiated in that direction. Usually, the polarization of an antenna remains relatively constant throughout the main lobe, but varies considerably in the minor lobes. It is convenient to define a spherical coordinate system associated with an antenna as illustrated in Figure 1-8. The polarization ellipse for the direction (θ, ϕ) is shown inscribed on

FIGURE 1-8 Polarization ellipse in relation to the antenna coordinate system (after⁷ © IEEE 1979)

the spherical shell surrounding the antenna. It is common practice to choose \mathbf{u}_θ (the unit vector in the θ direction) as the reference direction. The tilt angle is then measured from \mathbf{u}_θ toward \mathbf{u}_ϕ . The sense of polarization is clockwise if the electric field vector traverses the ellipse from \mathbf{u}_θ toward \mathbf{u}_ϕ , as viewed in the direction of propagation and counterclockwise if the reverse is true.

In many practical situations, such as antenna measurements, it is convenient to establish a local coordinate system. Usually, the u_3 axis is the direction of propagation; the u_1 axis is horizontal; and the u_2 axis is orthogonal to the other two so the unit vectors are related by $\mathbf{u}_1 \times \mathbf{u}_2 = \mathbf{u}_3$. The tilt angle is measured from \mathbf{u}_1 . When an antenna receives a wave from a particular direction, the response will be greatest if the polarization of the incident wave has the same axial ratio, the same sense of polarization, and the same spatial orientation as the polarization of the antenna in that direction. This situation is depicted in Figure 1-9, where E_t represents a transmitted wave (antenna polarization) and E_m represents a matched incident wave. Note that the sense of polarization for E_t and E_m are the same when viewed in their local coordinate system. Also, note that the tilt angles are different because the directions of propagation are opposite. As depicted in Figure 1-9, τ_t is the tilt angle of the transmitted wave and τ_m is the tilt angle of the polarization-matched received wave; they are related by

$$\tau_m = 180^\circ - \tau_t \quad (1-22)$$

The polarization of the matched incident wave, as just described, is called the *receiving polarization* of the antenna.

When the polarization of the incident wave is different from the receiving polarization of the antenna, then a loss due to polarization mismatch occurs. Let

$$\eta_p = \text{polarization efficiency (unitless)}$$

where η_p is the ratio of the power received by the antenna to the power received when polarization of the incident wave is matched to the receiving antenna polarization.

The Poincaré sphere, shown in Figure 1-10, is a convenient representation of polarization states. Each possible polarization state is represented by a unique point on the unit sphere. Latitude represents axial ratio, with the poles being circular polarizations; the upper hemisphere is for left-handed sense, and the lower hemisphere is for right-handed sense. Longitude represents tilt angles from 0 to 180°. An interesting feature of the Poincaré sphere is that diametrically opposite points represent orthogonal polarizations.

FIGURE 1-9 Relation between polarization properties of an antenna when transmitting and receiving (after⁷ © IEEE 1979)

FIGURE 1-10 Polarization states on the Poincaré sphere (after⁷ © IEEE 1979)

The Poincaré sphere is also convenient for representing polarization efficiency. In Figure 1-11, W represents the polarization of an incident wave, and A_r is the receiving antenna polarization. If the angular distance between the points is 2ξ , then the polarization efficiency is

$$\eta_p = \cos^2 \xi \quad (1-23)$$

FIGURE 1-11 Receiving polarization of an antenna A_r for an incident wave polarization W

1.7 DIRECTIVITY PATTERNS FROM CONTINUOUS LINE SOURCES

According to Huygens' and the equivalence principle (see Section 1.2), the radiation of arbitrary antennas can be characterized by considering equivalent source current distributions. The simplest source distributions are the electric and magnetic point sources considered in Section 1.3. More degrees of freedom toward the realization of particular directivity properties are provided by continuous line sources that can, for instance, be used to characterize the radiation behavior of linear wire antennas.

For line sources, the current distribution (electric and/or magnetic) is considered to be a function of only a single coordinate. The directivity pattern $E(u)$ resulting from a given distribution is simply related to the distribution by a finite Fourier transform,^{5,9,10} given by

$$E(u) = \frac{\ell}{2} \int_{-1}^{+1} f(x) e^{jux} dx, \quad (1-24)$$

where

$f(x)$ = relative shape of source distribution over aperture as a function of x

$u = (\pi\ell\lambda) \sin \phi$

ℓ = overall length of aperture

ϕ = angle measured from normal to aperture

x = normalized distance from normal to aperture $-1 \leq x \leq 1$

The simplest type of line source distribution is the uniform distribution where $f(x) = 1$ along the aperture and is zero elsewhere. The directivity pattern for such an antenna is (see Chapter 3)

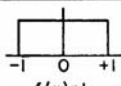

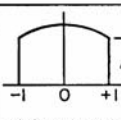

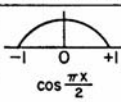

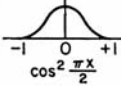

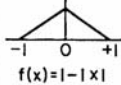

$$E(u) = \ell \frac{\sin u}{u} = \ell \frac{\left[\left(\frac{\pi\ell}{\lambda} \right) \sin \phi \right]}{\left(\frac{\pi\ell}{\lambda} \right) \sin \phi} \quad (1-25)$$

This type of directivity pattern $20 \log_{10} |E(u)|$ is of interest because all field contributions add in phase, giving the highest gain without cancellation effects.⁵ However, sidelobe levels are high, and the intensity of the first sidelobe is only 13.2 dB less than the maximum.

The intensity of the sidelobe levels can be reduced considerably by tapering the aperture distribution so the amplitude drops off smoothly from the center of the aperture to its edges. There are an unlimited number of possible distributions. However, a few simple types of distributions are typical and illustrate how the beamwidth, sidelobe level, and relative gain vary as a function of the distribution. Table 1-1 gives the important characteristics of several distributions having a simple mathematical form.

Of considerable interest is the manner in which the sidelobes fall off as the angle from the main beam increases or as u increases. For the uniform distribution that has a discontinuity in both the function and its derivatives at the edge of the aperture, the sidelobes decrease as u^{-1} . For the gable distribution or cosine distribution, both of which are continuous at the edge of the aperture but that have discontinuous first derivatives, the far-out sidelobes fall off as u^{-2} . For the cosine-squared distribution that has a discontinuous second derivative, the far-out sidelobes fall off as u^{-3} . Many distributions (obtained in practice) can be approximated by one of simpler forms or by a combination of simple forms.

TABLE 1-1 Line-Source Distributions

TYPE OF DISTRIBUTION $-1 \leq x \leq 1$	DIRECTIVITY PATTERN $E(u)$	HALF POWER BEAMWIDTH IN DEGREES 	ANGULAR DISTANCE TO FIRST ZERO 	INTENSITY OF 1st SIDELobe db BELOW MAX.	GAIN FACTOR
 $f(x) = 1$	$\ell \frac{\sin u}{u}$	$50.8 \frac{\lambda}{\ell}$	$57.3 \frac{\lambda}{\ell}$	13.2	1.0
 $f(x) = 1 - (1 - \Delta)x^2$	$\ell (1 + \Delta) \frac{\sin u}{u}$ $\Delta = (1 - \Delta) \frac{d^2}{du^2}$	$\Delta = 1.0$ $50.8 \frac{\lambda}{\ell}$.8 $52.7 \frac{\lambda}{\ell}$.5 $55.6 \frac{\lambda}{\ell}$ 0 $65.9 \frac{\lambda}{\ell}$	$57.3 \frac{\lambda}{\ell}$ $60.7 \frac{\lambda}{\ell}$ $65.3 \frac{\lambda}{\ell}$ $81.9 \frac{\lambda}{\ell}$	13.2 15.8 17.1 20.6	1.0 .994 .970 .833
 $\cos \frac{\pi x}{2}$	$\frac{\pi \ell}{2} \frac{\cos u}{(\frac{\pi}{2})^2 - u^2}$	$68.8 \frac{\lambda}{\ell}$	$85.9 \frac{\lambda}{\ell}$	23	.810
 $\cos^2 \frac{\pi x}{2}$	$\frac{\ell}{2} \frac{\sin u}{u} \frac{\pi^2}{\pi^2 - u^2}$	$83.2 \frac{\lambda}{\ell}$	$114.6 \frac{\lambda}{\ell}$	32	.667
 $f(x) = 1 - x $	$\frac{\ell}{2} \left(\frac{\sin \frac{u}{2}}{\frac{u}{2}} \right)^2$	$73.4 \frac{\lambda}{\ell}$	$114.6 \frac{\lambda}{\ell}$	26.4	.75

For instance, suppose you wanted to find the directivity pattern of a cosine-squared distribution on a pedestal, i.e., a combination of a uniform distribution and a cosine-squared distribution given by

$$f(x) = C + \cos^2 \frac{\pi x}{2} \quad (1-26)$$

The resulting directivity pattern is then obtained directly by superposition to obtain the direction pattern:

$$E(u) = C \ell \frac{\sin u}{u} + \frac{\ell}{2} \frac{\sin u}{u} \frac{\pi^2}{\pi^2 - u^2} \quad (1-27)$$

Note that the sidelobes and other characteristics of the pattern must be obtained from the new directivity pattern and cannot be interpolated from Table 1-1. By choosing the proper relative intensities of a uniform distribution and a cosine-squared distribution, it is possible to obtain a theoretical sidelobe level that is very low. For instance, if $C = 0.071$, then the intensity of the largest sidelobe will be 43 dB less than the maximum of the main beam with a half-power beamwidth given by $76.5\lambda/\ell$, a value that is somewhat lower than that of the cosine-squared distribution by itself.

In practice, it is not easy to synthesize prespecified continuous line-source distributions. Consider, for instance, a linear wire antenna; the electric current distribution along the wire is determined to fulfill Maxwell's equations under the constraint of the given boundary

FIGURE 1-12 (a) Linear wire antenna geometry, (b) Current distributions according to Eq. 1-28, and (c) corresponding field radiation patterns in arbitrary $\phi = \text{const.}$ planes (linear scale) for the first three resonances

conditions and cannot, therefore, be shaped arbitrarily. Good approximation of the current can be done, however, to study radiation from specific antennas.

In the following considerations, focus will be on a linear center-fed dipole wire antenna of length $2l$ aligned along the z axis, as illustrated in Figure 1-12a. The characteristics of the corresponding monopole antenna of length l over a perfectly conducting plane can be obtained by applying image theory.^{1,3}

As a first approximation, the thin wire antenna can be replaced by the z directed current distribution

$$I(z) = I_0 \sin(k(l - |z|)) \quad (1-28)$$

defined along the wire length. The corresponding electric field intensity in the far-field is³

$$\mathbf{E}(r) = \frac{jI_0}{2\pi r} \frac{\mu_0}{\epsilon_0} e^{-jk_0 r} \left[\frac{\cos(k_0 l \cos\theta) - \cos(k_0 l)}{\sin\theta} \right] \hat{\theta} \quad (1-29)$$

and can be used to derive an approximate far-field pattern. Obviously, the pattern is omnidirectional, and its θ dependence varies with antenna length. The θ dependence (in linear scale) of the field radiation pattern is illustrated in Figure 1-12c for three different wire lengths, with the corresponding current distributions according to Eq. 1-28 as depicted in Figure 1-12b. The radiation resistance can be calculated by integrating the total radiated power and relating it to the appropriate input current at the antenna port.^{1,3} Evaluating this expression gives the resistance as depicted in Figure 1-13.

Wire antennas are usually operated close to their resonance lengths $2l/\lambda = 0.5, 1, 1.5, 2, \dots$, where $2l/\lambda = 0.5, 1.5, \dots$ corresponds to the current resonance with low radiation resistance. Lengths $2l/\lambda = 1, 2, \dots$ result in voltage resonance with high radiation resistance. The lowest-order resonance $2l/\lambda = 0.5$ is associated with a radiation resistance of approximately 73Ω . Difficulties due to nulls in the current distributions for voltage resonances can be overcome by a modified higher-order current distribution.³¹ Figure 1-14

³ Extensive studies of linear wire antennas, even with realistic geometric dimensions, are presented in R. W. P. King's *The Theory of Linear Antennas*.¹² Approximate integral equation solutions are the basis for characterizing the various antenna parameters and results for a large variety of parameters are given.

FIGURE 1-13 Wire antenna radiation resistance obtained from the current distribution of Eq. 1-28 (normalized to I_0)

FIGURE 1-14 King-Middleton¹² second-order impedances for different values of l/a (see Figure 1-12). The numbers given next to the dots are the l/λ values.

illustrates the complex input impedance of the wire antenna for different l/a ratios and l/λ values.[§] You can see that thicker antennas have smaller impedance oscillations resulting in larger bandwidths. Also, the impedance curves show a slight shift of the reactance to the capacitive range.

A large collection of numerical computer codes, often based on the method of moments^{1,11} (see Chapter 59 on numerical techniques), is now available for analysis, design, and optimization of many wire antenna types.

1.8 DIRECTIVITY PATTERNS FROM AREA SOURCE DISTRIBUTIONS

Area source distributions serve as a radiation model for many antenna types, especially for those with radiation in a particular direction. Insight into various antenna characteristics can be gained from the consideration of simple aperture shapes such as rectangular, circular, or elliptical apertures.

Rectangular Apertures

The directivity pattern of an area distribution is found in a similar manner to that used for line-source distributions, except the aperture field is integrated over two dimensions instead of one dimension. If the aperture distribution is given by $f(x, y)$, where x and y are the two coordinates, then the directivity pattern is given by

$$E(\theta, \phi) = \iint f(x, y) e^{jk_0 \sin \theta (x \cos \phi + y \sin \phi)} dx dy \quad (1-30)$$

The difficulty of evaluating this expression depends on the form of the distribution function. For many antenna types, such as the rectangular horn, for example, the distribution function is separable, that is

$$f(x, y) = f(x)f(y)$$

The directivity patterns in the principal planes are readily determined for the separable case because the pattern in the xz plane is identical to the pattern produced by a line-source distribution $f(x)$, whereas the pattern in the yz plane is identical to the pattern produced by a line-source distribution $f(y)$. If the distribution function is not separable, the integral must be evaluated either analytically, graphically, or numerically.

Circular Apertures

An antenna that is used frequently in microwave applications is a *paraboloid* having circular symmetry. The radiation pattern can be computed by projecting the field distribution

[§] The curves in Figure 1-14 represent the King-Middleton second-order impedances and are drawn from the numerical data in *The Theory of Linear Antennas*.¹²

on the paraboloid to a plane at the opening of the paraboloid and computing the directivity pattern due to the plane aperture:

$$E(u, \phi') = a^2 \int_0^{2\pi} \int_0^1 f(r, \phi') e^{j u r \cos(\phi - \phi')} r dr d\phi' \quad (1-31)$$

where

a = radius at outside of aperture

p = radius at any point inside aperture

$r = p/a$

$u = (2\pi a/\lambda) \sin \theta = (\pi D/\lambda) \sin \theta$

$D = 2a$ = aperture diameter

$f(r, \phi')$ = the normalized aperture distribution function

The coordinates are shown in Figure 1-15.

The simplest forms of aperture distributions to evaluate are those in which the distribution is independent of the angular coordinate ϕ' but depends only on the radial coordinate r . The integral for the directivity pattern then becomes

$$E(u) = 2\pi a^2 \int_0^1 f(r) J_0(ur) r dr \quad (1-32)$$

When the distribution is constant, the integral is evaluated to give

$$E(u) = 2\pi a^2 \frac{J_1(u)}{u} \quad (1-33)$$

Antenna engineers frequently need to evaluate the directivity pattern for an illumination that tapers down toward the edge of the aperture. One function, which is convenient for representing the aperture distribution, is

$$f(r) = (1 - r^2)^p \quad (1-34)$$

This function behaves in a similar fashion to the n th-power distributions, as discussed for the line-source case (Section 1.7). When the exponent increases, the distribution becomes more tapered and more concentrated to the center of the aperture. When the exponent decreases and approaches zero, the distribution approaches uniform illumination.

FIGURE 1-15 Coordinates for a circular aperture

Evaluating the directivity pattern, gives

$$E(u) = 2\pi a^2 \int_0^1 (1-r^2)^p J_0(ur) dr$$

$$= \pi a^2 \frac{2^p p! J_{p+1}(u)}{u^{p+1}} = \frac{a^2}{p+1} \Delta_{p+1}(u), \quad (1-35)$$

where the Bessel functions $J_{p+1}(u)$ and the lambda function $\Delta_{p+1}(u)$ are available in tabular form.¹³

The principal characteristics of the directivity patterns are given in Table 1-2 for the cases $p = 0, 1, 2$. Comparison of the patterns for the uniformly illuminated circular aperture (i.e., when $p = 0$) with results for the uniformly illuminated line source (Section 1.7) shows that the circular aperture has a lower sidelobe level and a broader beamwidth. This is expected because projections of the circular-aperture illumination onto a line produce an equivalent line source that is no longer uniform but has some degree of tapering.

Elliptical Apertures

In some applications, an elliptically shaped reflector is used to permit control of the relative beamwidth in the two principal planes and to control the sidelobes by shaping the reflector outline. Computation of the directivity patterns for the aperture shape can be carried out by knowing the Fourier components of the illumination function over the aperture.

Realization of Continuous Aperture Distributions

In practice, continuous aperture distributions of large extent are realized by *horn, reflector, or lens antennas*.

TABLE 1-2 Circular-Aperture Distributions

TYPE OF DISTRIBUTION $0 \leq r \leq 1$	DIRECTIVITY PATTERN $E(u)$	HALF POWER BEAMWIDTH IN DEGREES 	ANGULAR DISTANCE TO FIRST ZERO 	INTENSITY OF 1st SIDELOBE db BELOW MAX.	GAIN FACTOR
 $f(r) = (1-r^2)^0 = 1$	$\pi a^2 \frac{J_1(u)}{u}$	$58.9 \frac{\lambda}{D}$	$69.8 \frac{\lambda}{D}$	17.6	1.00
 $f(r) = (1-r^2)$	$2\pi a^2 \frac{J_2(u)}{u^2}$	$72.7 \frac{\lambda}{D}$	$93.6 \frac{\lambda}{D}$	24.6	0.75
 $f(r) = (1-r^2)^2$	$8\pi a^2 \frac{J_3(u)}{u^3}$	$84.3 \frac{\lambda}{D}$	$116.2 \frac{\lambda}{D}$	30.6	0.56

Horn antennas (see Figure 1-16) are among the oldest and most popular microwave antennas. They can deliver 10 to 30 dB directivity, and their robust metallic constructions and waveguide feeds permit high-power handling. Horns are, therefore, often used as feeds for reflector antennas realizing even larger apertures. Horns are extensions of the widely used microwave guiding devices, such as rectangular and circular hollow waveguides in a natural manner (see Figure 1-16). To achieve matching from the waveguide to free-space, the hollow waveguide is tapered to a larger opening called the *aperture*. The effective aperture of the antenna (Section 1.4) is almost identical to the geometric aperture of the horn.

The equivalent aperture source distributions are typically used for extracting the radiation properties of horn antennas. These sources are an approximation found from the guided wave field arriving at the horn's aperture. Smaller beamwidths and larger directivities can be expected for horns with larger cross-section apertures, a consequence of the Fourier transformation relation between aperture distributions and far-field patterns. However, the maximum achievable directivity is limited due to phase errors of the aperture source distributions caused by the curved phase fronts in the tapered part of the horn antenna. Phase error corrections can be realized by using lenses in the horn aperture or by connecting the horn to a parabolic reflector (see Figures 1-17, 1-18, 1-19).

Another important concept in designing horn antennas is *corrugation*. Corrugations are grooves on the waveguide walls and are equivalent to introducing anisotropic boundary conditions on these walls. These anisotropic conditions offer additional degrees of freedom for controlling the radiation pattern and have been shown to lead to lower cross polarizations, higher aperture efficiencies, and more symmetrical far-field patterns.

The E plane sectoral horn is tapered only in the plane containing the E field (of the lowest-order rectangular waveguide mode), and the H plane sectoral horn is tapered in the corresponding plane containing the H field. Correspondingly, the pyramidal horn is tapered in both planes, and horns that are extensions of a circular waveguide are referred to as conical horn antennas. Further details on the analysis and practical realization of horn antennas can be found in Chapter 14 and the literature.^{1,2,14}

FIGURE 1-16 Common electromagnetic horn antennas: (a) E plane horn, (b) H plane horn, (c) pyramidal horn, (d) conical horn

FIGURE 1-19 (a) Delay lens with index of refraction > 1 and (b) fast lens with index of refraction < 1

From the preceding paragraphs and especially with knowledge of the Fourier transform relation between far-field patterns and aperture distributions, you can observe that high-gain antennas with small beamwidths typically require large (equivalent) aperture source distributions. Even though large apertures can be realized, however, unavoidable phase errors, as in the case of horn antennas, restrict achievable gain and correspondingly the effective aperture. A way to overcome this issue is to use a secondary device for shaping the phase fronts of the radiated or received waves. Metallic reflectors (curved metallic surfaces) serve this purpose and have been used since the early days of antennas to realize high gains. There are many different reflector types² ranging from linear reflector elements over flat metallic sheets to more complicated shapes such as corner reflectors, circular reflectors, hyperbolic reflectors, elliptic reflectors, and the more commonly used parabolic reflectors. Next, we briefly discuss parabolic reflectors. For other reflector types, refer to Chapter 15 on reflector antennas and the literature.^{1,2,15}

Figure 1-17 depicts the cylindrical and spherical parabolic reflectors. Both utilize the unique feature of the parabola to adjust the ray path lengths so that spherical waves emanating from the focal point generate fields of the same phase on the reflector aperture after reflection from the reflector surface. As a result, the rotationally symmetric paraboloid gives rise to very narrow patterns. Highly directive antennas can be realized by placing a primary line source in the focal line of a cylindrical paraboloidal reflector or a point source (a horn) at the focus of a paraboloid. Of course, these primary sources should be directed toward the reflector. Because the feed causes undesirable blockage and distortions to the main beam (a situation that worsens due to collateral equipment around the feed), subreflectors are introduced to place the feed at different locations. Shown in Figure 1-18 are classical *Cassegrain* and *Gregorian* double-reflector arrangements illustrating this concept. Cassegrain antennas use a hyperbolic subreflector whereas Gregorian reflectors employ an elliptical subreflector. Both subreflector types are usually designed so the feed or new focus can be located close to the primary reflector permitting feeding of the source at the focus through a hole in the primary reflector. Electromagnetic analysis of reflector antennas usually follows the principles of geometrical and physical optics, or geometrical theory of diffraction^{1,2,11,16} to account for edge diffraction.

Two different analysis techniques are often employed for reflector analysis: the aperture distribution and current distribution methods. For the latter, the electric currents are found directly on the reflector dishes, and the radiated fields are calculated by integrating these currents (see Section 1.3). In the aperture distribution method, equivalent currents are derived and placed on a planar aperture in front of the reflector, as illustrated in Figure 1-17. The radiated fields are then found by integrating these equivalent currents. As noted earlier, aperture blocking by the primary feed or the subreflector reduces antenna efficiency. Also, the blockage gives rise to higher sidelobe levels and cross-polarization effects. These blockages can be circumvented by reshaping the reflector so the feed is offset from the center of the aperture,¹⁷ often below or outside of the aperture view.

Similar to reflector antennas, *lens antennas* provide a means of shaping phasefronts of electromagnetic waves and influencing wave propagation in certain directions. Lens antennas can be divided into *delay lenses* and *fast lenses* (see Figure 1-19).² In a delay lens medium, the electromagnetic path length is increased (refractive index $n > 1$), whereas in a fast lens medium, the electromagnetic path length is decreased inside the lens (refractive index $n < 1$). Lenses may also be divided among *dielectric* and *metal-plate* lenses. Dielectric lenses consist of natural dielectrics or artificial dielectrics. Metal-plate lenses consist of parallel metallic plates realizing parallel-plate waveguides between the individual plates. *H* plane metal-plate lenses have metallic plates parallel to the *H* field of the electromagnetic wave and lead to $n > 1$. In contrast, the *E* field metal-plate lenses have the plates parallel to the *E* field resulting in $n < 1$. As noted earlier, lens antennas are often used to form collimating beams and thus increase the gain of microwave antennas. In this context, their purpose is to transform spherical or cylindrical wavefronts into planar wavefronts, and this is the reverse of focusing plane waves into a focal line or point (see Figure 1-19).

In contrast to reflector antennas, lens antennas do not have difficulties with aperture blocking and allow for beam scanning over relatively large angles. They also provide for additional design freedom since wave propagation is influenced by refraction at both the surfaces and the refractive index inside the medium, which can be adjusted as required (for instance by using layered designs). However, the corresponding design process is more complex when compared to metallic reflector antennas. Difficulties with lenses are caused by reflections at the two surfaces and losses in the lens material. Nevertheless, surface reflections can be reduced by matching layers or surface roughness. Analysis and design procedures for lens antennas are typically based on geometrical optics (Fermat's principle), physical optics, and related approaches such as the geometrical theory of diffraction. Details on the analysis of lens antennas and on the various classes of such antennas can be found in the literature^{1,2,11,16} and in Chapter 18 on lens antennas.

Recently, ideal lenses with arbitrarily good focusing properties have been discussed. Such lenses should be realizable by the use of so-called metamaterials with a refractive index of -1 .¹⁸

1.9 FUNDAMENTALS OF ANTENNA ARRAYS

The radiation and receiving characteristics of antennas can be shaped by synthesizing certain equivalent source distributions. Because it is difficult to control continuous aperture currents or fields, discrete configurations are often used, leading to the concept of *antenna arrays*. Putting the elements of an antenna array in a certain pattern and adjusting the amplitude and phase of the individual antenna elements appropriately allows for the synthesis of arbitrary aperture sources. These behave quite similarly to continuous aperture distributions (provided certain rules with respect to element spacing are followed). Design difficulties often arise due to coupling among array elements. Consequently, the amplitude and phase of the individual array elements cannot be adjusted independently from one another. The driving-point impedance of an individual element might differ considerably from its self-impedance because of the mutual coupling with other array elements. In a multi-element array, a way to relate the terminal voltages and element currents is

$$\begin{aligned} V_1 &= I_1 Z_{11} + I_2 Z_{12} + \cdots + I_n Z_{1n} \\ V_2 &= I_1 Z_{12} + I_2 Z_{22} + \cdots + I_n Z_{2n} \\ &\vdots \\ V_n &= I_1 Z_{1n} + I_2 Z_{2n} + \cdots + I_n Z_{nn} \end{aligned} \quad (1-36)$$

where

- V_n = impressed voltage at the n th element
- I_n = current flowing in the n th element
- Z_{nn} = self-impedance of the n th element
- $Z_{mn} = Z_{nm}$ = mutual impedance between m th and n th elements

The driving-point impedance for element 1 is found from the ratio of the impressed voltage to the current and is obtained from the previous equation as follows:

$$Z_{1\text{input}} = \frac{V_1}{I_1} = Z_{11} + \frac{I_2}{I_1} Z_{12} + \cdots + \frac{I_n}{I_1} Z_{1n} \quad (1-37)$$

The reader can see that the input or driving-point impedance of a particular element is not only a function of its own self-impedance but also a function of the relative currents

FIGURE 1-20 (a) Equally spaced linear and (b) two-dimensional array configurations

flowing on the other elements and of mutual impedance between elements. In an array in which the current distribution is critical, it is necessary to determine the input impedance from the previously described relationship and to design the feed system to match the input impedance rather than the self-impedance.**

To account for element coupling in the design, rigorous numerical methods^{1,4,11} must be employed. However, for simplicity, in the following array, coupling will be neglected because the main focus is the introduction of some basic concepts in array design.

A very basic and important array configuration is that of an equally spaced linear array of N identical elements on a straight line, as illustrated in Figure 1-20(a). The element spacing is d , and a linear phase progression is assumed for the element excitation currents. The total electric field intensity \mathbf{E}_{tot} in the far-field is given by

$$\begin{aligned} \mathbf{E}_{\text{tot}}(\theta, \phi) &= \mathbf{E}_{el}(\theta, \phi) \sum_{n=0}^{N-1} a_n e^{jn(k_0 d \cos \theta - \alpha)} \\ &= \mathbf{E}_{el}(\theta, \phi) \sum_{n=0}^{N-1} a_n e^{jn\psi} = \mathbf{E}_{el}(\theta, \phi) f(\psi) \end{aligned} \quad (1-38)$$

where $\psi = k_0 d \cos \theta - \alpha$ and \mathbf{E}_{el} refers to the array element pattern. Also, a_n is the amplitude of the individual array elements; α is the phase progression from one element to the next; and k_0 is the wavenumber of free-space. If all excitation currents are equal in amplitude ($a_0 = a_1 = a_2 = \dots = a_{N-1}$), the array factor $f(\psi)$ becomes

$$f(\psi) = a_0 \sum_{n=0}^{N-1} e^{jn\psi} = a_0 \frac{1 - e^{jN\psi}}{1 - e^{j\psi}} \quad (1-39)$$

** Some examples of this are given in "The Effect of a Periodic Variation in the Field Intensity Across a Radiating Aperture."¹⁹ See Chapter 3 for more information.

This can be simplified to obtain the normalized form

$$f_0(\psi) = \frac{f(\psi)}{Na_0} = \frac{\sin \frac{N\psi}{2}}{N \sin \frac{\psi}{2}} \quad (1-40)$$

where $f_0(\psi)$ is maximum when $\psi = 0$. For broadside radiation, $\alpha = 0$ must hold, implying that $\theta = \pi/2$. To scan the array beam toward other directions, α must be selected so that $k_0 d \cos \theta = \alpha$, resulting in

$$\theta = \theta_{\max} = \cos^{-1} \left(\frac{\alpha}{k_0 d} \right) \quad (1-41)$$

as the angle of the maximum array radiation. The direction of maximum radiation can be adjusted by controlling α , and this is a concept characteristic to scanning arrays. In practical phased arrays, the phase of the individual array elements is controlled electronically to allow for much more flexible, faster, and reliable array scanning as compared to traditional mechanical steering approaches.

Modern mobile communication systems are increasingly employing phased arrays at base stations (in conjunction with sophisticated signal processing algorithms) to expand the base station customer capacity and reduce interference among adjacent stations. In the wireless industry, such antennas are typically referred to as *smart* or *adaptive antennas*.

If the spacing d between the array elements becomes greater than half a wavelength λ_0 , the denominator of $f_0(\psi)$ can have further zeros, resulting in additional array radiation beams. These beams are referred to as grating lobes. In practice, suppressing such parasitic lobes is required.

Figure 1-21 illustrates several array patterns derived from $f_0(\psi)$. These show the characteristic narrow main beam and a larger number of sidelobes as the number of array

FIGURE 1-21 Linear array pattern factors f_0 (array element spacing $d = 0.4\lambda_0$)

elements increases. Lower sidelobe levels can be achieved by tapering the excitation of the array elements. Several techniques, such as the binomial or the popular Chebyshev methods (see Chapter 3 on array design) are used for controlling the sidelobe levels and the main beamwidth.

Next, we consider the 2D linear array in Figure 1-20b. This array has M elements along the z -axis and N elements along the y -axis. The array elements are equally spaced with corresponding spacings of d_z and d_y and associated linear phase progressions of α_z and α_y . For the computation of the array factor $f(\theta, \psi)$, the 2D array can be viewed as M equally spaced linear arrays along the z -direction. It is given by

$$\begin{aligned} f(\theta, \phi) &= \sum_{n=0}^{N-1} \sum_{m=0}^{M-1} a_{mn} e^{jn(k_0 d_z \cos \theta - \alpha_z)} \\ &= \sum_{n=0}^{N-1} \sum_{m=0}^{M-1} a_{mn} e^{jn\psi_z} e^{jm\psi_y} \end{aligned} \quad (1-42)$$

where $\psi_z = k_0 d_z \cos \theta - \alpha_z$ and $\psi_y = k_0 d_y \sin \theta - \alpha_y$. Assuming the amplitudes of all array elements to be identical ($a_{00} = a_0 = \dots = a_{M-1N-1}$) and applying the same manipulations as in the case of the linear array, the normalized array factor $f_0(\theta, \psi) = f_0(\theta, \psi)/(MNa_{00})$ is found to be

$$f_0(\theta, \phi) = \frac{\sin\left(\frac{Nk_0 d_z}{2} \cos \theta\right) \sin\left(\frac{Mk_0 d_y}{2} \sin \theta \sin \phi\right)}{N \sin\left(\frac{k_0 d_z}{2} \cos \theta\right) M \sin\left(\frac{k_0 d_y}{2} \sin \theta \sin \phi\right)} \quad (1-43)$$

In general, the amplitude of every array element can be chosen independently in order to shape arbitrary array patterns. Conventional beam-shaping techniques try to approximate directivity patterns known from continuous aperture distributions (Sections 1.7 and 1.8). More recently, digital signal processing techniques are employed to realize a large variety of applications such as angle of arrival detection (see Chapter 47 on direction finding), tracking, interferer suppression, and adaptive signal to interference improvement.

A severe disadvantage of linear array configurations is their restricted field of view. Reasonable beam-shaping and scanning can be achieved by modifying the array element amplitudes. However, many arrays have restricted angular range. This drawback can be overcome by array configurations *conforming* to curved surfaces. As such, every array element may have a different geometrical orientation, and suitable element amplitude directivity behavior can be a difficult task. Beam-shaping techniques have been developed incorporating digital signal-processing techniques for the necessary flexibility to achieve desirable designs (see Chapter 22).

A disadvantage of an array conformed to a curved surface is that not all antenna elements contribute to the radiated fields in a particular direction. Thus, more array elements are required to achieve certain requirements with respect to beamwidths and sidelobe suppression. An example of a singly curved conformal array antenna is shown in Figure 1-22.

FIGURE 1-22 Singly curved array antenna realized with patch antenna elements (*Courtesy of FGAN e.V., Wachtberg, Germany*)

Another array configuration are *volumetric arrays*. To avoid shadowing of the individual array elements, the grid must be relatively thin, and reasonable beam-shaping is achieved only by randomly distributing array elements to suppress grating lobes due to large element spacing. In principal, all array elements can radiate in all directions. However, practical realization of volumetric arrays is not easy, and the choice of suitable array elements and feeding techniques is restricted. An example of a volumetric array is depicted in Figure 1-23.

1.10 BASIC CONCEPTS IN MOBILE COMMUNICATIONS

Mobile communications is an area where unguided electromagnetic waves and antennas play an important role. The goal is to offer communication links between any place on earth without limiting user mobility. Given the restricted spectrum availability, the need for frequency reuse, particularly in densely populated areas, creates special challenges that are most efficiently resolved within terrestrial mobile communication systems. However, the requirement to cover remote regions makes essential the use of satellite systems in the overall strategy.

Terrestrial mobile communication systems are usually based on cellular principles, where the mobile terminal communicates with a fixed base station. Alternative strategies can, for instance, establish a connection via a network of mobile terminals only (*ad-hoc networks*); however, the focus here will be on cellular techniques. The fundamental issue in mobile communications is the restricted availability of frequency bands. Therefore, system design must aim at a high spectrum efficiency expressed in Erlang per square meter per Hertz and given by

$$\eta_s = \frac{\text{number of reuses}}{\text{coverage area}} \times \frac{\text{number of channels}}{\text{bandwidth}} \times \frac{\text{time the channel is busy}}{\text{total time of channel}} \quad (1-44)$$

where one busy communication channel is equivalent to the traffic of one Erlang.

The basic behavior of cellular designs is often studied in the context of hexagonal cell coverage, as illustrated in Figure 1-24, where the assumption is that the base station is located at the center of a cell. The idea is to reuse a given set of communication channels or frequencies (in those cells) that are sufficiently apart from each other so that co-channel interference remains within acceptable limits. Code division multiple access (CDMA) techniques assign relatively broad frequency bands to individual cells. Those techniques, however, can often work with the same frequency in neighboring cells since channel separation is achieved on a code level and frequency planning may be replaced or supplemented by code planning. Therefore, discuss reuse considerations on the channel level. The group of cells not employing channel reuse is called a *cluster*. Such a cluster is depicted in Figure 1-24 as a grey-shaded area and consists of seven cells.

FIGURE 1-24 Hexagonal cellular pattern with a reuse factor of 7

The number of cells N comprising a cluster is, in general, given by

$$N = i^2 + ij + j^2 \quad (1-45)$$

where i and j are integers, with $N=7$ being a popular number of cells per cluster. Obviously, you can increase the mobile system's capacity (i.e., cellular phone users) by increasing the number of available channels (bandwidth) or the spectrum efficiency η_s . Because bandwidth is restricted, the logical approach is to achieve better spectrum efficiency through channel reuse. This implies smaller cell sizes and consequently a greater number of cells in a given coverage area. For example, a single cell can be subdivided into several smaller cells, or a cell can be divided into sectors by using directional antennas to avoid installing additional base stations. Typical cell dimensions used to cover wide rural regions or suburban areas are referred to as *macrocells*. In densely populated urban regions, however, cells must often be installed at the street level with base stations located below building roofs. Such cells are often called *microcells*, and even smaller cells (restricted to a single site or the interior of a building) are referred to as *picocells*.

The key to designing complex cellular mobile communication systems is electromagnetic wave propagation within individual cells. Propagation models are essential for evaluating modulation and coding schemes and their associated signal power within the service area or the interference that may be caused outside the service area. Even when adaptive power control is used at the transmitter, a thorough understanding of the relevant wave propagation mechanisms in the terrestrial environment is necessary. For propagation above a smooth ground, a simple ray-optical model including two rays is sufficient for modeling wave propagation. In general, ray approaches are based on high-frequency assumptions, typically fulfilled at mobile communication frequencies (greater than 400 MHz).

The two-ray model includes a direct ray representing free-space propagation and a ray reflected at the earth's surface. Assuming the earth's surface to be planar, the two-ray model gives the following pathloss:

$$L_p = 20 \log \left(\frac{\lambda}{4\pi r} \right) + 20 \log \left| 1 + R_b \frac{r}{r_b} e^{-j2\pi/\lambda (r_b - r)} \right| \quad (1-46)$$

L_p is the ratio of received to transmitted power in dB, where both antennas are assumed to be isotropic. The involved parameters are λ , or the free-space wavelength; r , or the path length of the direct ray; r_b , or the path length of the reflected ray; R_b , or the plane wave reflection coefficient at the reflection point.

Figure 1-25 compares L_p as given to single/direct-ray (free-space) and four-ray models for different transmitter antenna heights. The typical two-ray interference pattern is clearly identified close to the transmitter. Also, at great distances from the transmitter, the two-ray model predicts a pathloss that has a constant slope of 40 dB/decade versus a pathloss with a slope of 20 dB/decade predicted by the single-ray or free-space model. Figure 1-25 also shows that changing the transmitter antenna height can control the coverage range of the base station.

Microcells or picocells are often designed at the street level, and for these cases, the two-ray model for flat earth can be improved by including ray reflections from the street side walls. For example, Figure 1-25 shows four-ray pathloss curves to model a 16 m-wide street canyon, where contributions from the two sidewall-reflected rays are added to the two-ray results. Again, the usual interference patterns are observed close to the transmitter. However, at great distances from the transmitter, the guiding effect of the street canyon results in a pathloss that is even less than that predicted by the single-ray or free-space model. Also, the height of the transmitter antenna no longer influences the pathloss at great distances.

FIGURE 1-25 Pathlosses for different ray models over flat ground. Scalar computations with a receiver antenna height of 2.4 m, different transmitter antenna heights h_t , and all reflection coefficients set to -1 . The given four-ray models also include sidewall-reflected rays at each side of a 16 m broad street canyon.

Previously, we discussed simple propagation models. However, real-world terrestrial mobile communication channels are characterized by complicated wave propagation mechanisms. The received signal is composed of an extremely large number of different multiply reflected, diffracted, refracted, or scattered wave contributions, and a purely deterministic description of the radio channel might be impossible. Therefore, most receiver power or receiver field strength determination methods are designed to predict the corresponding median values as a first characterization of the channel properties. The fading behavior of the mobile radio channel is described by means of statistical methods where fast- and slow-fading mechanisms are distinguished. Fast-fading can often be characterized by Rayleigh or Rice probability distributions, and slow-fading normally behaves as lognormal distributed with standard deviations of several dBs.

Further insight into the behavior of a mobile radio channel can be gained from measured or predicted impulse responses, as shown in Figure 1-26, which typically consist of various signal contributions arriving at the receiver after different delay times and with different Doppler shifts due to moving transmitter and receiver antennas as well as scattering objects. Information that can be obtained from the impulse responses are the relative signal powers and delay spreads for the different signal contributions. Both the Doppler shifts and the delay spreads are essential in the design of mobile communication systems. Often, test sequences are included in the transmitted signals, which allow for the estimation of important channel parameters and can be used for channel equalization.

Modern terrestrial communication systems often utilize several transmit and/or receive antennas (*multiple input multiple output (MIMO)*) to achieve improved signal to noise and/or signal to interference ratios of the communication links. The different antennas can be arranged in closely spaced array configurations suitable for the realization of deterministic beam-forming strategies (see Section 1.8). Another strategy tries to arrange the antennas

FIGURE 1-26 Measured impulse response of different mobile radio channels in Garmisch Partenkirchen, Germany (hilly terrain). The measurement bandwidth was 6 MHz at the given carrier frequency f_0 . The measured data shown were provided by Deutsche Telekom, Darmstadt, Germany.

such that their transmitting or receiving characteristics become uncorrelated, leading to so-called diversity techniques. Further information on terrestrial mobile communication systems can be found in Chapter 22 on conformal antennas.

2.1 INTRODUCTION TO FREQUENCY BANDS

The spectrum chosen for use in either military or commercial applications often depends on a number of factors, including regulatory requirements or licenses that designate bands for certain uses. Depending on the application, the frequency band selected may also depend on antenna size, propagation distance, or environment. Over time, a number of different designations for frequency bands have been developed. For comparison, each of these band designations is shown in Table 2-1. Historically, some of the band groupings have differed, in part based on the application(s) intended, such as radar, electric countermeasures, and so on. The most commonly used designations are also listed in Table 2-1.

As mentioned, one of the factors to consider when selecting a band is the propagation characteristics of the band. Figure 2-1 shows attenuation as a function of wavelength or frequency. Attenuation is also a function of a number of factors that include both scattering losses and absorption losses. In general, lower frequencies tend to propagate farther and to transmit better under non-line-of-sight conditions. However, lower frequency antennas also tend to be larger because antenna size scales with frequency, creating a number of trade-offs that must be considered. For example, the military might select a lower frequency for operation so communication over mountain ranges is optimized; however, the lower frequency creates challenges in implementing an antenna that is a

reasonable size. In other cases, the military might select a band where propagation is limited for security or frequency re-use opportunities. An example of such a band is the V-band around 60 GHz. This band is well suited to short-range applications, but the implementation of low-cost antennas that perform suitably can be difficult due to the high frequency of operation, though the antennas will be relatively small for a given antenna gain compared to the lower frequencies.

The trade-offs associated with the use of various frequency bands have been studied extensively over time, and certain characteristics and applications are now commonly linked to specific frequency bands. Table 2-2 lists a number of frequency bands along with their common characteristics and uses. In general, the lower frequency bands tend to be used for longer range, lower bandwidth applications while higher bands tend to be used more often for shorter range applications that require higher bandwidth. In the case of radar, the higher frequency bands are often selected for higher resolution and the antennas take up less volume at these higher frequencies.

In the case of television and radio broadcasts, the selected bands tend to be lower, such as VHF and UHF, because the broadcasting company will likely want to cover an entire city or an even greater area with a single transmit site. The specific frequency band used by a particular station also depends on its license through a regulatory agency such as the Federal Communications Commission (FCC), which designates specific channels or bands with well-defined separation between them to avoid interference with broadcast services. The bands and channels used for AM/FM radio and television broadcast in the U.S. are shown in Table 2-3. The separation between the bands, sometimes called *guard bands*, help prevent interference between adjacent bands, but these bands were established decades ago. With continuing advances in communications technology and equipment, and the move toward digital television, the FCC is looking at different ways of thinking about the bandwidth per channel and the guard bands. In transmitting digital television, less bandwidth is required than

TABLE 2-2 Common Frequency Bands: Characteristics and Typical Applications

Band	Characteristics	Applications
HF	Long-distance links possible with ionosphere reflections	Ocean vessel communications, telephone, telegraphy, long-range aeronautical communications, amateur radio communications, military communications
VHF	Ionosphere reflections possible at the lower end of the frequency band	Television and FM broadcasting, air traffic control, radio navigation, military communications
UHF	Tends to require more line-of-sight toward the high end of the frequency band	Television broadcasting, radar, mobile phones and radios, satellite communications, global positioning systems (GPSs), wireless LANs, wireless PANs, military communications
SHF	Atmospheric absorption at highest frequencies can be significant	Radar, microwave links, land mobile communications, satellite communications, direct broadcast satellite (DBS) television
EHF	Line-of-sight propagation only toward the high end of the band, subject to atmospheric absorption, and best suited to shorter range applications	Radar, secure and military communications, satellite links, gigabit per second backhaul (1–2 km), future wireless PANs
Optical / IR	Significant atmospheric absorption, typically will not penetrate fog, line-of-sight only	Optical communications, fiber-optical links, very short range wireless communications, building-to-building high-speed wireless connections

with analog, but the bandwidth does depend on the resolution or definition of the signal. In the future, digital television may evolve toward either one very high-definition digital signal or multiple lower definition signals for multiple television channels in what was one signal when transmitting analog. Advances in communications technology have also led to the discussion of the potential use of the guard bands for other applications since advances may allow for their use without interfering with the original broadcast channels.

37	608–614 MHz	61	752–758 MHz		

Broadcast Frequencies

AM Radio = 535 kHz–1605 kHz (MF) 107 Channels each with 10 KHz separation

TV Band I (Channels 2–6) = 54 MHz–88 MHz (VHF)

FM Radio Band II = 88 MHz–108 MHz (VHF) 100 Channels each with 200 KHz separation

TV Band III (Channels 7–13) = 174 MHz–216 MHz (VHF)

TV Bands IV & V (Channels 14–69) = 470 MHz–806 MHz (UHF)

In addition to commercial broadcast channels, a number of amateur radio bands have been established. These bands also tend to be at lower frequencies since it is usually desirable to have propagation over long distances to communicate with other amateur radio sites, as shown in Table 2-4. The successful use of the higher bands depends on the proximity of other amateur sites because they tend to propagate over shorter distances.

TABLE 2-4 Amateur Radio Bands

Band	Frequency
160 m	1.8–2.0 MHz
80 m	3.5–4.0 MHz
40 m	7.0–7.3 MHz
20 m	14.0–14.35 MHz
15 m	21.0–21.45 MHz
10 m	28.0–29.7 MHz
6 m	50.0–54.0 MHz
2 m	144.0–148.0 MHz
	220–225 MHz
	420–450 MHz
	1215–1300 MHz
	2300–2450 MHz
	3300–3500 MHz
	5650–5925 MHz

2.2 FREQUENCIES AND TECHNOLOGIES OF INTEREST FOR MILITARY APPLICATIONS

Military and commercial communication needs have similarities and differences, as shown in Figure 2-2 and Figure 2-4, later in the chapter in Section 2.3. One area of commonality is that both stem from the demand for quick and efficient delivery of information. However, the pace at which they develop their communication technologies and their dynamic motivations for doing so are where the two sectors diverge and are continuously evolving. In some cases, the commercial sector's communication development outpaces the military's because its driving force is economic and its market is vast. In other instances, military technology outpaces the commercial sector since performance may be more important than low cost for critical equipment. In some ways, the two sectors are merging with the military's technology, research, and development organizations such as Defense Advanced Research Projects Agency (DARPA), Office of Naval Research (ONR), Naval Research Laboratory (NRL), Air Force Research Laboratory (AFRL), and Space and Naval Warfare (SPAWAR) Systems Command, moving toward leveraging more commercial technology as the military increases its demand for commercial sector innovations to bring its communication systems up to 21st-century standards. The military can optimize its communication systems by complementing available commercial technology with newly developed, customized technology providing a superior hybrid solution.

Most terrestrial communication systems used by the military and the commercial market, including HF, VHF, and UHF radios, utilize conventional monopole and dipole antennas that are electrically small but long enough to provide adequate gain and the largest possible coverage area. Most *satellite communication (satcom)* systems depend on mechanically rotated reflector dish antennas that provide high gain and a narrow beam from a relatively simple parabolic antenna structure in order to illuminate the orbiting satellites with precision accuracy. These antenna structures are, however, still large and can be used as a visual cue in the identification of the communication system's location. In the case of the military,

FIGURE 2-2 Wireless technologies for military communication systems

inconspicuous communication vehicles are essential to protecting communication capability and the personnel both operating the system and receiving its intelligence support. The commercial sector also benefits from reduced antenna architectures because the savings in real estate allow for additional communication systems to be installed. In the case of cellular infrastructure, reduced size systems can translate into reduced recurring costs because less space may need to be leased at the site's location.

Methods for reducing antenna size include using planar antenna geometries similar to those of microstrip antennas with parasitic shorting structures,²⁻⁵ high dielectric substrates,⁶ geometrical variations of the antenna architecture including slots,⁷⁻¹⁰ and active element integration into the antenna.

Connectivity on today's battlefield is of such great importance that communication development programs are being forced to develop rapidly. Multifunction communication platforms are being built to satisfy the need for multiple radio access and centralized intelligence distribution using a router methodology that consolidates the information from several different radio sources and redistributes it to personnel using the appropriate communication system. A multitude of processing and communication systems are utilized together to keep all mission participants apprised of tactical and strategic information as it becomes available, allowing command decisions to be handed down as required.

The radios used by the military vary in frequency and constitute a range of frequencies that span from the HF to Ka-band, as shown in Figure 2-3.

Tactical radios in the HF frequency, including the PRC-150 from 2 MHz to 30 MHz, are important in transmitting voice and limited data over long distances by pumping large amounts of power (20–100 W) through substantially large monopole antennas. These tactical radios also fall within the civilian Ham radio frequencies, which also require large amounts of power to operate.

VHF radios operate at slightly higher frequencies from 30–88 MHz, providing for increased bandwidth to transmit more data over the same long distances. This is true for the SINCGARS RT-1523E radio system, which also pumps large amounts of power through a large monopole antenna to extend the range of its transmissions.

Radios that operate at UHF, which also include the L-band and S-band from 300 MHz to 3 GHz, provide increased bandwidth capability and faster data rates than HF and VHF systems but at the expense of reduced transmission range. Operating at these higher frequencies also scales down the size of the antennas used to Tx/Rx signals, which reduces the visibility of mobile communication platforms. As presented in Figure 2-2, the PRC-148, PRC-117, PSC-5D, RT-1720 EPLRS, and VRC-99 radios all operate at these frequencies. The range of the systems are reduced due to the limitations of shorter

FIGURE 2-3 Military communications frequency spectrum

wavelength transmissions, but this shortfall is more than compensated for because larger bandwidths are available and long-distance data transfers can be achieved by using relays to leapfrog signals between intermediate points and then on to remote positions.

Situational awareness reports that include highly detailed maps with reconnaissance pictures and even video are transmitted by tactical satellite radios operating at the C-, Ku-, and Ka-band. These frequencies are capable of penetrating through the ionosphere to orbiting satellites and then back down to other positions on earth that are over-the-horizon from the position of the originating source transmission. This over-the-horizon capability and increased bandwidth are major goals of the military and also of the commercial market, which means greater amounts of data can be sent more quickly to more distant locations thus providing needed intelligence for informed decision making.

This wide array of radio systems over the large frequency range increases military capability, especially when placed on a mobile platform, but at the cost of increased hardware including the radios themselves, networking equipment, power sources, and the antennas to perform the necessary signal propagation. This excessive amount of hardware is expensive and bulky, and in the case of the antennas, presents the problem of physically placing them on top of a small roof, deck, mast, or fuselage. Not only are there co-site signal propagation issues associated with multiple antennas for multiple communication systems, but also there is the burden of concealing the vehicle, ship, or aircraft's purpose from unwanted spectators. In order to decrease the visibility of the mobile platform as a target and maximize its carrying capacity, there is a need to scale down the size, weight, and volume of all components including the antennas. This requires antenna designs that use planar antenna technologies and allow for dual-band, multiband, and broadband multifunction capability.

2.3 FREQUENCIES AND TECHNOLOGIES OF INTEREST FOR COMMERCIAL APPLICATIONS

Commercial frequency bands and application technologies are driven by a number of factors but none more significant than cost. As previously discussed, this factor is more relevant for commercial applications than for military ones. The overall cost of a solution or service is a direct function of equipment cost but can also be affected by the spectrum selected for use. In some cases, licensing spectrums can be very expensive and that cost must eventually be passed on to the consumer by a service provider. One of the advantages of using the licensed spectrum is that there is recourse if another company or individual interferes with the spectrum. The unlicensed spectrum is typically open for use by anyone as long as the conditions and limits set by that country's regulatory agency, such as the FCC in the U.S., are adhered to, but there is no recourse if another user creates interference when using the spectrum in the same vicinity.

The backbone of communication is the allocated frequency bands that radio equipment use to transmit and receive its data, and there are various wireless networks and protocols used for management. Commercial wireless protocols are varied and continue to evolve from the present second-generation (2G) to third-generation (3G) and future fourth-generation (4G) network system protocols that provide expanded bandwidth and increased data-rate capability. The 2G protocols were based on low-band digital data signals that provided a vast improvement over the previous analog systems. The 3G protocols allow wideband digital data transfers for large video and data transmissions. The trend is toward multimedia services, and this trend has made possible podcasting and streaming video that were once tethered to Ethernet cable connections on desktop computers but are now accessible with wireless multimedia phones, personal digital assistants (PDA), and laptops.

FIGURE 2-4 Wireless technologies for commercial communication systems

The intermediate bridge between 2G and 3G is 2.5G, and it allows theoretically limited data transfer rates of up to 384 kbps, which is a significant increase from the previous 9.6–14.4 kbps capability of 2G. But, of course, theoretical limits are often just that—theoretical—when the reality is that 40–50 kbps is the nominal data rate.

In 2010–2015, 4G will succeed 3G and will offer increased data rates up to 100 Mbps while on the move and 1 Gbps while stationary for on-demand high-quality video transmissions and accelerated downloads. Several factors will contribute to 4G's succession, including the use of *Orthogonal Frequency Division Multiplexing (OFDM)* and *Orthogonal Frequency Division Multiple Access (OFDMA)* to more efficiently allocate resources between multiple users. Also, a network based solely on packet switching as opposed to the inefficient combined circuit-switched and packet-switched network is an improvement over 3G. Software-defined radio (SDR) receivers with wider bandwidth capability may also be used. In addition, 4G could be orchestrated using *pervasive networks* (a.k.a. ubiquitous computing) as first introduced by Mark Weiser,¹¹ which is a theoretical concept that allows multiple wireless technologies to be accessed simultaneously and information exchanged between them seamlessly while using 4G devices. To better manage the frequency spectrum allocation and transmission power utilized, pervasive networks will also use a *smart-radio* (a.k.a. cognitive radio) technology that decides the best frequency and power management.

Commercial wireless technologies include wireless cellular and wireless local area and personal area networks (WLAN, WPAN). WLAN systems typically operate in a range from 10–100 m while WPAN systems typically operate up to about 10 m. Cellular technologies have evolved from analog systems to today's higher capacity digital systems with increased speeds and capabilities. The system protocols deployed in the initial move to digital cellular, often referred to as 2G, varied greatly in method but all supported the common function of delivering information between users. The wireless protocols operate in the ~850/900/1800/1900/2100 MHz frequency bands, with the specific bands varying depending on the country, mode of operation, and cellular carrier. As shown in Figures 2-4 and 2-5, many digital protocols are in use today, such as time division multiple access (TDMA), code division multiple access (CDMA), Global System for Mobile Communications (GSM), digital communication systems (DCS), personal communication

Wireless Protocols	Transmission Rate (Mbps)	Effective Range (m)
802.15.3a UWB (disbanded)	50–500	1–10
802.11n	10–100	1–100
802.11a/g	5–50	1–100

Blackberry	≤0.1	50–50,000

FIGURE 2-5 Wireless protocols: their transmission rates (Mbps) and effective ranges (meters)

systems (PCS), and analog protocols that are still in use but in a diminishing capacity, for instance, Advanced Mobile Phone System (AMPS/NAMPS), Nordic Mobile Telephone (NMT), and Total Access Communication Systems (TACS). Worldwide today, GSM is the most widely used of these cellular protocols. Third-generation (3G) extensions of the digital protocols are emerging to increase bandwidth and data rates and include 3GSM, a 3G GSM network; CDMA2000, a 3G CDMA-based network; and General Packet Radio Services (GPRS). Some 3G protocols have been implemented in Asia already and are expected to be implemented in the U.S. and Europe in 2006–2007.

The 802.16 WiMAX protocol is one of the up-and-coming premier high-speed wireless broadband solutions that may provide greater than 70 Mbps data rates to high-density medium-size areas (1000–5000 m) such as city buildings, small and rural communities, and suburban malls. WiMAX operates at S-band and C-band frequencies and was first implemented into WiMAX indoor and outdoor modems in 2004 using orthogonal frequency division multiplexing. WiMAX will be further embedded into the wireless community's portable devices, including 3G and 4G ultra mobile PCs, over the next two to three years providing high-speed broadband wireless capability. However, WiMAX will still rely on an overlying wireless protocol, such as GSM or CDMA, to distribute the system over large city- and region-wide areas, causing some debate over how WiMAX will coexist with future cellular technologies if it is as widely deployed as expected.

WLAN and WPAN protocols (802.11 family) are also included in Figures 2-4 and 2-5 and are responsible for wireless data connections of various speeds and bandwidths to the internet for laptops, PDAs, and other wireless devices that operate in close proximity to one another. These include the 802.11 family operating at 2.4 GHz and 5 GHz. The 802.11 data rates continue to increase as well, with 802.11b offering 11 Mbps, 802.11a/b offering 54 Mbps, and the emerging 802.11n that's expected to offer data rates in excess of 100 Mbps, in part by utilizing multiple-input multiple-output (MIMO) communication techniques.

In addition, 802.15.4 ZigBee protocols, which allow devices to communicate low bandwidth and low data rate information between each other and achieve extremely long battery life, are expected to enable systems such as wireless sensor networks (WSNs) that can be deployed and left in place without maintenance for extended periods of time.

Bluetooth, which is covered under IEEE 802.15.1, is today's most widely deployed WPAN solution and is commonly used for wireless hands-free headsets for mobile phones. This area of wireless continues the trend toward higher speeds. There are some emerging technologies, however, that promise to move beyond the initial Bluetooth data rates of approximately 1 Mbps. Some of the potential solutions to offer very high speeds at short ranges include ultra wideband (UWB), dynamic frequency selection, cognitive radios, and higher-order modulation to achieve high throughputs in a limited spectrum with much higher spectral efficiency. Each of these potential solutions face technical challenges with some also confronting additional regulatory challenges. Dynamic frequency selection and cognitive radio, for example, may offer the shared use of large amounts of licensed spectrum, though it's not clear if regulatory bodies like the FCC and their equivalent in other countries will allow unlicensed users access to parts of the licensed spectrum or what the reaction will be from licensed users. UWB appears to be facing some regulatory challenges as Japan and Europe seem to have become more concerned with potential interference from using the full 3–10 GHz spectrum allowed in the U.S. and may limit its use to a subset of what the FCC has allowed. These bodies may limit wide scale deployment of UWB hardware to the resulting common worldwide spectrum, since a single solution for worldwide deployment is desirable for high-volume consumer electronics.

As reported by R. M. Emrick and J. L. Vokakis,¹² there is an excellent opportunity to use millimeter wave frequencies to propagate signals over short ranges supporting very high data rates from greater than 100 Mbps to 1–5 Gbps using available V-band spectrum at 60 GHz,

where there is 3 GHz of available unlicensed worldwide spectrum. Historically, the use of such high frequencies has been limited to specialized applications because of the high cost of implementation. Recent and ongoing advances in a number of technologies indicate that low-cost solutions utilizing these frequencies should be possible.¹³ Some early work indicates that Si technology transceivers can support the 60 GHz frequency band of operation and are economical enough to manufacture in large quantities for a large consumer market.^{14,15} Next-generation network interface cards (NIC) already support 1 Gbps transfer rates and USB2.0 and IEEE 1394 standards are in place for high-speed wireless capability, making the need for 60 GHz high-speed wireless hubs (or equivalent) more a question of when they will be needed rather than if they will be needed.

It is interesting to note that there is an overlap between the unlicensed bands worldwide in the V-band from 59–62 GHz, which will allow for 3 GHz of available bandwidth that can be readily used anywhere on the planet (see Figure 2-6). There is also a standard being developed in the form of IEEE 802.15.3c. Other spectrum purchases by supporting and competing 60 GHz technology companies are sure to occur outside this unlicensed band and will likely supplement the necessary bandwidth for a successful millimeter-wave high-speed broadband protocol.

Solutions utilizing this millimeter-wave spectrum for very high-speed connectivity may be “stand alone,” or they may be integrated with other wireless technologies where at least some of the system can be reused. Measured performance of an early proof-of-concept system is shown in Figure 2-7. In consumer electronics, typically acceptable bit error rates (BER) are around 10^{-6} . Using this BER, Figure 2-7 shows demonstrated data rates of about 3.5 Gbps at ranges of 5 m and 1 Gbps up to a range of 50 m. This performance is for point-to-point line-of-sight with a single antenna at the transmitter and receiver. In order to achieve acceptable performance for non-line-of-sight use, MIMO and antenna gain are most likely needed.¹²

As previously stated, the deployment of high-speed solutions using millimeter-wave frequencies can be stand alone or exist as an alternative mode in a multimode system that includes 802.11. The European Union funded a program called Broadway, which looked at a hybrid dual-frequency broadband wireless LAN access system at 5 GHz and 60 GHz to be implemented for urban hotspot coverage.¹⁶ This system is based on integrating HIPERLAN/2 OFDM technology at 5 GHz and an ad-hoc extension of it at 60 GHz called HIPERSHOT and would be an extension of the existing 5 GHz WLAN systems using new modes in the 59–65 GHz worldwide unlicensed frequency bands. Broadway could alternatively be used in combination with 802.11 solutions that exist and utilize the 2.4 GHz band.

FIGURE 2-6 Available unlicensed global spectrum in the V-band

FIGURE 2-7 Measured data rate vs. distance for an early proof of concept system,¹³ which shows the potential for very high data rates at distances traditionally within the WPAN ranges for point-to-point line-of-sight (after R. Emrick et al¹³ © IEEE 2005)

2.4 EXAMPLES OF FUNDAMENTAL ANTENNA TYPES USED IN MILITARY AND COMMERCIAL APPLICATIONS

The selection of an antenna for a specific application is typically driven by a number of factors including antenna size, which is associated with the particular frequency being utilized and the platform it will fit, the direction and distance over which the antenna needs to transmit its signal, and the antenna's operational environment, which can introduce many variables that are best handled by certain antenna designs.

There are a number of fundamental antenna types that are typical options when determining the best antenna for a given application and frequency band. There are, of course, variations of these antenna types that may, at times, include hybrid approaches providing for optimized solutions. Many antennas, such as monopoles and dipoles, are resonant antennas that generally have dimensions close to half a wavelength. These antennas are often simple structures with relatively narrow bandwidth. Broadband antennas, such as log-periodic antennas, typically have the largest dimension that is a half-wavelength at the lowest frequency of operation. Antennas like this become resonant across the full frequency of operation for greatly improved bandwidth. Aperture antennas tend to be used for higher gain, are typically several wavelengths in one or more dimensions, and can be implemented using a feed and reflector or an array of wire or printed elements.

Dipole and monopole wire antennas are the most basic types of antenna because of their simple structure and omnidirectional radiation capability. The impedance characteristics associated with these antennas have been investigated thoroughly, giving rise to general formulas for straightforward design. A monopole is an antenna that is mounted ideally on an infinite ground plane and can be characterized by a dipole antenna that is twice its size radiating in free space. A simple half-wave dipole is a center-fed driven antenna whose two conductors are opposite each other and perpendicular to the center feed. There are many different variations of these antennas including the cylindrical dipole, which has a length to diameter ratio of more than 15:1, biconical dipoles with conductors that flare out into cones, folded dipole

antennas that are formed by two cylindrical dipoles and driven by a pair of transmission lines, and sleeved dipoles and monopoles, which are doubly fed antennas with the current at a maximum at the center of the dipole or base of the monopole. Their omnidirectional radiation patterns are well suited for terrestrial LOS communications over vast distances.

Reflector antennas have high gain and are very directive making them well suited for earth-based stations communicating with satellites in orbit. Reflector designs can be planar, have a parabolic arc, or incorporate a design that uses neither of the aforementioned designs. Feed structures can be placed in front of the reflector or be fed from the back, depending on the reflector technology being implemented. Reflectors have superior gain and directivity but require large apertures that can be quite cumbersome to position, requiring mechanical control and closed loop tracking, such as conical scanning when the ground station is mobile or there is satellite movement in a low earth orbit (LEO). The components needed with this technology take up a significant amount of space, creating the need for alternate solutions.

Phased array antennas utilize multiple radiator elements uniformly spaced in linear or two-dimensional configurations, often half a wavelength apart, and their amplitude and phases are controlled to form a radiated beam of any desired shape for propagation in free space. Phased arrays are normally planar, making them low profile and they produce high-gain beams that are electronically steered, making them a viable replacement for large reflector antennas. Phase shifters are most often the technology of choice to manipulate the phase between radiators. One of the biggest challenges in implementing a phased array is cost; each element of the array typically requires extensive and costly electronics. Historically, phased arrays have been used for less cost-sensitive applications, but future implementation using digital beam forming, retrodirection, and/or other alternative methods, may allow for more widespread use in more cost-sensitive applications.

Printed microstrip-type antennas are used in many different commercial applications, including cell phones, WLAN networking cards, personal digital assistants, and GPS receivers. These applications typically operate at ranges that are within 1–10,000 m of the transmission and reception points. These antennas have inherently low gain and, in most cases, require amplification to increase range, but the relative ease of fabrication and low profile make them attractive candidates for small commercial and military handheld communication devices that have limited space for antenna apertures.

In the end, the selection of the ideal antenna for a given frequency band and application comes down to balancing the fundamental parameters that typically include size, cost, weight, and reliability. Achieving the right balance among these parameters is often far from trivial.

3.1 INTRODUCTION

Telecommunications services in which antennas occupy a prominent position have grown tremendously over the years. Antennas are ubiquitous devices in radio, TV, satellite, and mobile communications, and the economic and social impact of these services motivate engineers to improve antenna feasibility and performance. A single element antenna, due to its limited performance, is often not enough to meet technical needs for high gain, narrow and/or steerable beams, pattern nulls, and low sidelobes. An array of discrete elements can, however, cover most of these constraints. The antenna array is characterized by element type, geometry, and the required excitations. Mutual coupling between the elements is important in the array design. The elements are chosen, if possible, to be identical and parallel. Uniformly spaced linear arrays are the most practical ones.

In this chapter the properties of the various antenna arrays and many synthesis methods will be discussed.

3.2 ANTENNA ARRAY FACTOR AND ANTENNA INDICES

The approximation of the far field coming from an antenna¹ separates it into a function of the position r of the observation point and into a function-vector of its angles, θ and ϕ , of the spherical coordinate system. The far electric field of a typical antenna array element (see Figure 3-1) can be expressed as^{2,3}

$$E_n(r) \equiv -j\omega\mu \frac{e^{-j\beta r}}{4\pi r} f_n(\theta, \phi) \quad (3-1)$$

FIGURE 3-1 Geometry of a typical antenna array

The angular-dependent vector $f_n(\theta, \phi)$ presents the directional characteristics of the n th element.

Because the antenna array shown in Figure 3-1 contains N elements, the total electric field is

$$E(r) = \sum_{n=1}^N E_n(r) \quad (3-2)$$

As mentioned previously, the elements of the array are identical and, if possible, identically oriented. In this case, the current distribution of the elements is approximately the same. So, $f_n(\theta, \phi)$ is

$$f_n(\theta, \phi) = I_n f(\theta, \phi) \quad (3-3)$$

$f(\theta, \phi)$ characterizes the pattern of the element, and I_n is the excitation of the n th element of the array. By taking into account Eq. 3-1 to Eq. 3-3, the total electric field is

$$E(r) = -j\omega\mu \frac{e^{-j\beta r}}{4\pi r} f(\theta, \phi) \sum_{n=1}^N I_n e^{j\beta r_n \cos \xi_n} \quad (3-4)$$

which is $\cos \xi_n = \sin \theta \sin \theta_n \cos(\phi - \phi_n) + \cos \theta \cos \theta_n$, where (r_n, θ_n, ϕ_n) are the coordinates of a convenient reference point of the n th element. The summation of Eq. 3-4 is the *array factor* $AF(\theta, \phi)$:

$$AF(\theta, \phi) = \sum_{n=1}^N I_n e^{j\beta r_n \cos \xi_n} \quad (3-5)$$

$AF(\theta, \phi)$ actually presents the pattern of N isotropic point sources from the original array. Equation 3-5 then becomes

$$E(r) = -j\omega\mu \frac{e^{-j\beta r}}{4\pi r} f(\theta, \phi) AF(\theta, \phi) \quad (3-6)$$

Equation 3-6 states that, “An array of similar identically oriented elements has a pattern that can be expressed as the product of the element pattern and the array factor.” Since the element pattern is known, the main effort in antenna array design is the synthesis of the array factor.

One of the main characteristics of an antenna is its radiation pattern (see Figure 3-2). The pattern presents graphically the radiation properties that can be measured by moving a probe around the antenna when testing at a constant distance in the far field. If the probe moves in a plane, the pattern is known as the *plane pattern*. The plane pattern that contains the electric field vector is called the *E-plane pattern*. Correspondingly, the plane pattern that contains the magnetic field vector is the *H-plane pattern*.

FIGURE 3-2 Plane and 3D patterns of an antenna

The radiation characteristics of an antenna array are measured in terms of the indices given in Chapter 1. These indices are the directivity $D(\theta_0, \phi_0)$, the gain $G(\theta_0, \phi_0)$, the signal-to-noise ratio SNR , the radiation efficiency η , the quality factor Q , the half power (or 3 dB power) beamwidth $HPBW$, the first null beamwidth BW_{null} , the sidelobe level SLL , and the bandwidth of the antenna array.

3.3 LINEAR ARRAYS

A practical array that consists of a number of elements set up along a straight line is called a *linear array* (see Figure 3-3). The pattern of a linear array can be expressed in well-known polynomial forms.

The array factor $AF(\theta, \phi)$ of the linear array shown in Figure 3-3 depends only on the angle θ and is written as

$$AF(\theta) = \sum_{n=0}^{N-1} I_n e^{j\beta d_n \cos \theta} \quad (3-7)$$

If the elements are equally spaced in terms of distance d , then Eq. 3-7 yields to

$$AF(\theta) = \sum_{n=0}^{N-1} I_n e^{j\beta n d \cos \theta} = \sum_{n=0}^{N-1} I_n z^n \quad (3-8)$$

$$z = e^{j\beta d \cos \theta} \quad (3-9)$$

For $0 \leq \theta \leq \pi$, $AF(\theta)$ is a polynomial of z , which moves on a unit circle.³ The phase is bounded between $-\beta d$ and $+\beta d$, and the bounded region is called the *visible region*.

Uniform Linear Arrays

Uniform linear arrays (ULA) consist of equally spaced elements with equal magnitude and progressive phases. In Eq. 3-7, $I_n = (e^{j\alpha})^n$. Equation 3-7 is then transformed to¹

$$AF(\psi) = e^{j(N-1)\psi/2} \frac{\sin(N\psi/2)}{N \sin(\psi/2)} \quad (3-10)$$

$$\psi = \beta d \cos \theta - \alpha \quad (3-11)$$

FIGURE 3-3 A linear array of N elements

The basic characteristics of the ULA array factor can be summarized as follows:

1. Maximum values occur at $\psi = \pm 2k\pi$, where $k = 0, 1, 2, \dots$
2. Nulls of the array are located at $\psi = \pm 2k\pi/N$, where $k = 1, 2, 3, \dots$ and $k \neq N, 2N, 3N, \dots$
3. The 3 dB points of the array factor occur when

$$AF(\psi) = \pm \frac{\sqrt{2}}{2} \Rightarrow |AF(\psi)|^2 = \frac{1}{2} \Rightarrow 10 \log |AF(\psi)|^2 = -3 \text{ dB}$$

which gives $N\psi/2 = \pm 1.391 \text{ rad}$.

4. Secondary maxima (minor lobes) occur when

$$\psi = (2k+1)\pi/N, \quad \text{where } k = 1, 2, 3, \dots$$

The first minor lobe is located at $\psi = \pm 3\pi/N$ with

$$|AF(\psi)| = \frac{1}{N \sin \frac{3\pi}{2N}} = SLL$$

For a phase shift $\alpha = \beta d \cos \theta_0$, the array beam can be steered in the direction θ_0 . For an end-fire array, $\alpha = \mp \beta d$. Apart from the ordinary end-fire array, there is also the Hansen-Woodyard (HW) array, which is more directive.² With HW arrays, the progressive phase shift α is

$$\alpha = \mp \left(\beta d + \frac{2.94}{N} \right) = \mp \left(\beta d + \frac{\pi}{N} \right) \quad (3-12)$$

For HW arrays,

$$|\psi| = \pi \begin{cases} \text{for } \theta = \pi \text{ if maximum occurs at } \theta = 0 \\ \text{for } \theta = 0 \text{ if maximum occurs at } \theta = \pi \end{cases} \quad (3-13)$$

$$d = \frac{\lambda}{4} \left(1 - \frac{2.94}{\pi N} \right) = \frac{\lambda}{4} \left(1 - \frac{1}{N} \right) \quad (3-14)$$

Table 3-1 presents the sidelobe locations and levels for broadside ULAs with different numbers of elements. The directivity of broadside ULAs is presented in Table 3-2.

A linear array with maximum at $\theta = \theta_0$ and half-power beamwidth θ_H must have

$$\theta_0 > \cos^{-1} \left(\cos^2 \frac{\theta_H}{2} \right) \quad (3-15)$$

$$N \frac{d}{\lambda} = 0.4428 \left[\frac{2(1 + \cos \theta_H)}{|\sin^4 \theta_0 - (\cos \theta_H - \cos^2 \theta_0)|^2} \right]^{1/2} \quad (3-16)$$

In end-fire arrays where $\theta_0 = 0^\circ$, Eq. 3-16 is modified to

$$N \frac{d}{\lambda} = \frac{0.4428}{1 - \cos \frac{\theta_H}{2}} \quad (\text{Ordinary}) \quad (3-17)$$

$$N \frac{d}{\lambda} = \frac{0.1398}{1 - \cos \frac{\theta_H}{2}} \quad (\text{Hansen - Woodyard}) \quad (3-18)$$

Chebyshev Arrays

Uniformly spaced linear arrays with nonuniform excitation of the elements can use Chebyshev polynomials.³ These arrays produce the desired *SLL* and are called *Chebyshev arrays*.

A Chebyshev polynomial $T_m(x)$ of m th order and an independent variable x is an orthogonal polynomial. In region $-1 \leq x \leq 1$, it contains equal ripples with amplitudes between $+1$ and -1 . $T_m(x)$ outside the region $(-1, +1)$ rises exponentially. $T_m(x)$ is actually expressed as

$$T_m(x) = \begin{cases} \cos(m \cos^{-1} x) & |x| \leq 1 \\ \left(\frac{x}{|x|}\right)^m \cosh(m \cosh^{-1} |x|) & |x| > 1 \end{cases} \quad (3-19)$$

TABLE 3-2 Directivities for Broadside ULAs of Isotropic Elements

N	Spacing (λ)							
	0.125	0.250	0.375	0.500	0.625	0.750	0.875	1.000
4	1.28	2.16	3.11	4.00	4.84	5.58	5.29	4.00
5	1.45	2.70	3.83	5.00	6.12	6.97	7.68	5.00
6	1.67	3.17	4.63	6.00	7.30	8.54	9.52	6.00
7	1.93	3.64	5.34	7.00	8.61	10.10	11.22	7.00
8	2.20	4.16	6.10	8.00	9.84	11.55	12.82	8.00
9	2.48	4.68	6.86	9.00	11.07	12.99	14.42	9.00
10	2.74	5.17	7.59	10.00	12.41	14.43	16.10	10.00

For zero and first order as well as for the recursion relation, you have

$$\left. \begin{aligned} T_0(x) &= 1, T_1(x) = x \\ T_m(x) &= 2xT_{m-1}(x) - T_{m-2}(x) \end{aligned} \right\} \quad (3-20)$$

These equations are used to create the Chebyshev polynomials of any order.

Dolph-Chebyshev Arrays Dolph⁴ has found that maximum directivity for a given *SLL* can be obtained using Chebyshev polynomials. Their equal ripples describe the sidelobes, and the exponential increase beyond $|x| = 1$ gives the main lobe. The excitation distribution is symmetrical in the centre of the array (see Figure 3-4).

The independent variable of the Chebyshev polynomial is

$$x = x_0 \cos(\psi/2) \quad (3-21)$$

At $x = x_0$, the Chebyshev polynomial takes its maximum value R :

$$T_m(x_0) = R \quad \text{or} \quad x_0 = \cosh\left(\frac{1}{m} \cosh^{-1} R\right) \quad (3-22)$$

Nulls of $T_m(x)$ are located at

$$x_k = \pm \cos \frac{(2k-1)\pi}{2m}, \quad \psi_k = \pm 2 \cos\left(\frac{x_k}{x_0}\right) \quad \text{where } k = 1, 2, \dots, m \quad (3-23)$$

By using the expression $z_k = e^{j\psi_k}$, you can find I_k from the following polynomial expression⁵:

$$AF(\theta) = C \prod_{n=1}^m (z - z_n) = C \sum_{k=0}^m I_k z^k \quad (3-24)$$

The order of the Chebyshev polynomial is equal to the total number of array elements minus one.

An example of two patterns (broadside and intermediate) of a 14-element array with *SLL* = -25 dB is given in Figure 3-5. The polynomial is $T_{13}(x)$. For $R = 25$ dB, it is $R = 10^{25/20} = 17.7828$ and $x_0 = 1.038$.

FIGURE 3-4 The geometry of an even and an odd element linear array

FIGURE 3-5 Pattern of a 14 element Dolph-Chebyshev array with $SLL = -25$ dB and $d/\lambda = 0.5$. (a) broadside array $\theta_0 = 0^\circ$, (b) intermediate array with maximum at $\theta_0 = 60^\circ$.

In Chebyshev arrays, there is a maximum permissible interelement distance d_{\max} to avoid grating lobes:

$$\frac{d_{\max}}{\lambda} = 1 - \frac{\cos^{-1}(1/x_0)}{\pi} \quad (3-25)$$

x_0 is the distance where the maximum of the Chebyshev polynomial occurs.

The ratio of the Dolph array's $HPBW$ over a uniform array ($HPBW_u$) of the same length gives the broadening factor f , which is found to be¹

$$f = \frac{(HPBW)}{(HPBW_u)} = 1 + 0.632 \left[\frac{2}{R} \cosh \sqrt{(\cosh^{-1} R)^2 - \pi^2} \right]^2 \quad (3-26)$$

f is valid in the range of $-60 \text{ dB} \leq SLL \leq -20 \text{ dB}$ and for scanning near broadside arrays.

Estimation of the directivity D with the help of the factor f is of the form:¹

$$D = \frac{2R^2}{1 + (R^2 - 1)f \frac{\lambda}{Nd}} \quad (3-27)$$

For the general case, the $HPBW$ is given approximately by

$$HPBW \cong 10.3^\circ \frac{\lambda}{Nd} \sqrt{s + 4.52} \csc \theta_0 \quad (3-28)$$

s is the absolute value of the SLL in dB, and θ_0 is the scan angle. Also, the directivity D is

$$D = \frac{2R^2}{1 + R^2 \frac{\lambda}{Nd} \sqrt{\frac{\ln(2R)}{\pi}} \cdot \sin\left(\beta \frac{d}{2}\right)} \quad (3-29)$$

General Chebyshev Arrays Dolph's method is suitable for $d \geq \lambda/2$, but it fails to give the optimum design for $d < \lambda/2$. To solve the problem Riblet⁶ devised a Chebyshev method by using odd numbers of elements. Moreover in J. N. Sahalos' *Orthogonal Methods for Array Synthesis, Theory and the ORAMA Computer Tool*,³ a method is presented that covers Riblet's method. In this method, the independent variable is expressed by

$$x = a \cos(\beta d \cos \theta + \alpha) + b \quad (3-30)$$

The coefficients a , b , and α are found from three different angles, θ_1 , θ_2 and θ_3 , of the pattern that corresponds to three values of x , the x_1 , x_2 , and x_3 . The visible region is in $\min(x_1, x_2, x_3) \leq x \leq \max(x_1, x_2, x_3)$.

$$\left. \begin{aligned} x_1 &= a \cos(\beta d \cos \theta_1 + \alpha) + b \\ x_2 &= a \cos(\beta d \cos \theta_2 + \alpha) + b \\ x_3 &= a \cos(\beta d \cos \theta_3 + \alpha) + b \end{aligned} \right\} \quad (3-31)$$

From Eq. 3-31, you then have

$$\tan \alpha = \frac{\sin y_{21} - \lambda \sin y_{31}}{\lambda \cos y_{31} - \cos y_{21}} \quad (3-32)$$

$$\left. \begin{aligned} y_{21} &= \beta \frac{d}{2} (\cos \theta_2 + \cos \theta_1) \\ y_{31} &= \beta \frac{d}{2} (\cos \theta_3 + \cos \theta_1) \\ \lambda &= \frac{(x_2 - x_1) \sin \left[\frac{\beta d}{2} (\cos \theta_3 - \cos \theta_1) \right]}{(x_3 - x_1) \sin \left[\frac{\beta d}{2} (\cos \theta_2 - \cos \theta_1) \right]} \end{aligned} \right\} \quad (3-33)$$

$$a = \frac{x_2 - x_1}{\cos(\beta d \cos \theta_2 + \alpha) - \cos(\beta d \cos \theta_1 + \alpha)} \quad (3-34)$$

$$b = x_1 - a \cos(\beta d \cos \theta_1 + \alpha) \quad (3-35)$$

I_k is found by using a polynomial expression as in Eq. 3-24.⁵ For $(2m - 1)$ elements, $T_m(x)$ is used. Nulls of $T_m(x)$ are located at

$$x_k = \pm \frac{(2k-1)\pi}{2m}, \quad \psi_k = \pm \cos^{-1} \left(\frac{x_k - b}{a} \right) \quad k = 1, 2, \dots \quad (3-36)$$

The pattern of an 11 element broadside array with $SLL = -20$ dB and $d/\lambda = 0.3$ is shown in Figure 3-6. $T_5(x)$ is used and the present method offers a more directive pattern than the Dolph array. More examples of the design of General Chebyshev patterns can be found in J. N. Sahalos.^{3,7,8}

FIGURE 3-6 Pattern of an 11 element Dolph and General Chebyshev array with $SLL = -20$ dB and $d/\lambda = 0.3$

Taylor Distributions

Continuous distributions are useful when creating patterns with low sidelobes.¹ A discrete array coming from the appropriate sampling of a continuous distribution (line source) can give a similar pattern. Root matching is a suitable technique that offers satisfactory results. In root matching, the nulls of the patterns of the continuous distribution and the discrete array must be the same. If the patterns do not match with the desired accuracy, a perturbation technique⁹ in the discrete-element array is applied.

For a continuous line source, the array factor is called a *space factor* (SF). If L is the length, $I(z')$ and α are the amplitude distribution and phase progress along the line source, respectively, SF is expressed by

$$SF(\theta) = \int_{-L/2}^{L/2} I(z') e^{j(\beta \cos \theta - \alpha) z'} dz' = \int_{-L/2}^{L/2} I(z') e^{j\xi z'} dz' = \int_{-\infty}^{\infty} I(z') e^{j\xi z'} dz' \quad (3-37)$$

$I(z')$ is zero outside of $-L/2 \leq z' \leq L/2$. From Eq. 3-37, by using the Fourier transform, you obtain

$$I(z') = \frac{1}{2\pi} \int_{-\infty}^{\infty} SF(\theta) e^{-j\xi z'} d\xi \quad (3-38)$$

The desired $SF(\theta)$ needs a distribution that exists in $-\infty \leq z' \leq \infty$. However, if L is large enough, Eq. 3-38 can be used for the current distribution up to $(-L/2, L/2)$ within a certain error. Taylor gave a distribution, with an optimally low SLL for the first N sidelobes next to the main beam. Sidelobes, after the first N , gradually fall off in value. The SF of the Taylor

distribution comes from the Dolph-Chebyshev array if the elements of the array become infinite.¹⁰ It is

$$SF(u) = \frac{\cosh\left[\sqrt{(\pi A)^2 - u^2}\right]}{\cosh(\pi A)} \quad (3-39)$$

$$\left. \begin{aligned} u &= \pi \frac{L}{\lambda} (\cos \theta - \cos \theta_0) \\ \cosh(\pi A) &= R \end{aligned} \right\} \quad (3-40)$$

In practice, Taylor's distribution¹¹ is given by a space factor whose roots are the zeros of $SF(u)$. This distribution is called the *Chebyshev error distribution*. In addition, Taylor synthesized a pattern that has the first sidelobes at a certain level with the others decaying as the scan angle increases. Enough samples in the distribution may synthesize an array with its pattern having approximately similar characteristics.

Bayliss Distributions

Bayliss distributions¹² create patterns with their null along the boresight and the sidelobes at a given level. Bayliss' space factor is

$$SF(u) = u \cosh(\pi u) \frac{\prod_{n=1}^{\bar{n}-1} \left[1 - \left(\frac{u}{u_n} \right)^2 \right]}{\prod_{n=1}^{\bar{n}-1} \left[1 - \left(\frac{u}{n + \frac{1}{2}} \right)^2 \right]} \quad (3-41)$$

In this, $(\bar{n} - 1)$ defines the number of inner nulls, and u_n is given as a function of two quantities A and ξ_n .

$$u_n = \begin{cases} \left(\bar{n} + \frac{1}{2} \right) \left(\frac{\xi_n^2}{A^2 + \bar{n}^2} \right)^{1/2} & n = 1, 2, 3, 4 \\ \left(\bar{n} + \frac{1}{2} \right) \left(\frac{A^2 + n^2}{A^2 + \bar{n}^2} \right)^{1/2} & n = 5, 6, \dots, \bar{n} - 1 \end{cases} \quad (3-42)$$

Modified Taylor and Bayliss Patterns

Patterns based on the Taylor and Bayliss distributions can be modified to have their sidelobes at different levels. The space factors then take the more general form.⁵

(i) Taylor

$$SF(u) = C_0 \frac{\sin \pi u}{u} \frac{\prod_{n=\bar{n}_L-1}^{\bar{n}_R-1} \left(1 - \frac{u}{u_n} \right)}{\prod_{n=\bar{n}_L-1}^{\bar{n}_R-1} \left(1 - \frac{u}{n} \right)} \quad (3-43)$$

$$\left. \begin{aligned} u_n &= \bar{n}_R \frac{\sqrt{A_R^2 + \left(n - \frac{1}{2}\right)^2}}{\sqrt{A_R^2 + \left(\bar{n}_R - \frac{1}{2}\right)^2}} \\ u_n &= -\bar{n}_L \frac{\sqrt{A_L^2 + \left(n + \frac{1}{2}\right)^2}}{\sqrt{A_L^2 + \left(\bar{n}_L - \frac{1}{2}\right)^2}} \end{aligned} \right\} \quad (3-44)$$

in which \bar{n}_R and \bar{n}_L denote the transition roots of the right and left side, respectively, and A_R and A_L are the corresponding *SLL* parameters.

(ii) Bayliss

$$SF(u) = C_0 u \cos \pi u \frac{\prod_{n=-(\bar{n}_L-1)}^{\bar{n}_R-1} \left(1 - \frac{u}{u_n}\right)}{\prod_{n=-\bar{n}_L}^{\bar{n}_R-1} \left(1 - \frac{u}{n + \frac{1}{2}}\right)} \quad (3-45)$$

To synthesize the distribution, you start from an initial space factor $SF_0(\theta)$ with the *SLLs* on both sides being the average of the desired ones. In this case, the roots of Eq. 3-43 and Eq. 3-45, u_n^0 , are known, and you assume that

$$u_n = u_n^0 + \delta u_n \quad (3-46)$$

with δu_n being a small perturbation of u_n^0 . For $C = C_0 + \delta C$, the new space factor $SF(u)$ is then of the form

$$\frac{SF(u)}{SF_0(u)} - 1 = \frac{\delta C}{C_0} + \sum_{n=-(\bar{n}_L-1)}^{\bar{n}_R-1} \frac{\frac{u}{(u_n^0)^2}}{1 - \frac{u}{u_n^0}} \delta u_n \quad (3-47)$$

If the peak positions are u_m^p , then

$$\frac{SF(u_m^p)}{SF_0(u_m^p)} - 1 = \frac{\delta C}{C_0} + \sum_{n=-(\bar{n}_L-1)}^{\bar{n}_R-1} \frac{\frac{u_m^p}{(u_n^0)^2}}{1 - \frac{u_m^p}{u_n^0}} \delta u_n \quad (3-48)$$

With $\bar{n}_R + \bar{n}_L - 1$ being the number of lobes, this leads to a system of linear equations similar to the one in Eq. 3-48. The system is solved for $\delta C/C_0$ and for the $\bar{n}_R + \bar{n}_L - 2$ values δu_n ($\delta u_0 = 0$). The new values of u_n produce a pattern comparable to the desired one. If the desired and new patterns differ more than the minimum predefined amount, the process is repeated until the desired tolerance is achieved.

FIGURE 3-7 Patterns of (a) $N = 22$ elements based on the modified Taylor distribution (left), and (b) of $N = 23$ elements based on the modified Bayliss distribution; $d/\lambda = 0.5$, $\bar{n} = 6$, $SLL = -20$ dB with the three innermost lobes at -40 dB

For the Bayliss distribution you have

$$\frac{SF(u_m^p)}{SF_0(u)} - 1 = \frac{\delta C}{C_0} - \frac{\delta u_0}{u_m^p} + \sum_{n=-(\bar{n}_L-1)}^{\bar{n}_R-1} \frac{\frac{u_m^p}{(u_n^0)^2}}{1 - \frac{u_m^p}{u_n^0}} \delta u_n \quad (3-49)$$

This equation produces a system of $\bar{n}_R + \bar{n}_L$ unknowns, and the perturbation process is created in the same way as before. Sampling the distributions of the space factors, you obtain the corresponding arrays of discrete elements.

Figure 3-7 shows the patterns of two arrays taken by sampling two modified distributions with $\bar{n} = 6$, $SLL = -20$ dB, with the three innermost pairs of lobes at -40 dB.

3.4 PLANAR ARRAYS

Planar arrays are created from individual radiators positioned on a plane. They provide more variables and can give stricter constraints than linear ones. Also, they allow for three-dimensional mainbeam scanning. Planar arrays with their elements along a rectangular grid create rectangular arrays. In essence, two perpendicular linear arrays create a rectangular one. The array factor of an $M \times N$ rectangular array is

$$F(\theta, \phi) = \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} I_{mn} z_x^m z_y^n \quad (3-50)$$

In this, I_{mn} refers to the element excitations corresponding to the m th row and n th column. Also,

$$z_x = e^{j\beta d_x \sin\theta \cos\phi} \quad \text{and} \quad z_y = e^{j\beta d_y \sin\theta \sin\phi} \quad (3-51)$$

For an array with uniform excitation, the array factor is

$$|AF(\theta, \phi)| = \left| \frac{\sin(M\Psi_x/2)}{M \sin(\Psi_x/2)} \right| \left| \frac{\sin(N\Psi_y/2)}{N \sin(\Psi_y/2)} \right| \quad (3-52)$$

$$\left. \begin{aligned} \Psi_x &= \beta d_x \sin \theta \cos \phi + \alpha_x \\ \Psi_y &= \beta d_y \sin \theta \sin \phi + \alpha_y \end{aligned} \right\} \quad (3-53)$$

If d_x and/or d_y is $>\lambda$, grating lobes are created. They are produced when the in-phase addition of radiated fields happens in more than one direction. The main lobe and the grating lobes for planar arrays are located at

$$\Psi_x = \pm 2m\pi, \Psi_y = \pm 2n\pi, \quad m \text{ and } n = 0, 1, 2, \dots \quad (3-54)$$

α_x and α_y are independent to each other. From Eq. 3-53 and Eq. 3-54, the grating lobe direction (θ_{mn}, ϕ_{mn}) is

$$\tan \phi_{mn} = \left[\frac{\sin \theta_0 \sin \phi_0 \pm n\lambda/d_y}{\sin \theta_0 \cos \phi_0 \pm m\lambda/d_x} \right] \quad (3-55)$$

$$\sin \theta_{mn} = \left[\frac{\sin \theta_0 \sin \phi_0 \pm n\lambda/d_y}{\sin \phi_{mn}} \right] \quad (3-56)$$

The main lobe occurs for $m = n = 0$ where $\theta_{00} = \theta_0$ and $\phi_{00} = \phi_0$. A 3D pattern for 8×6 elements with $\alpha_x = \alpha_y = 0$ and $d_x = d_y = \lambda$ is given in Figure 3-8a. Due to large spacing, except for the maximum at $\theta_0 = 0$ and $\theta_0 = \pi$, grating lobes are created at $\theta = \pi/2$ and $\phi = 0, \pi/2, \pi, 3\pi/2$.

Rectangular arrays can be designed by also using nonuniform linear arrays. In Figure 3-8b the pattern of two Dolph-Chebyshev arrays with $SLL = -20$ dB for 8×6 elements with $d_x = d_y = \lambda/2$ is presented.

Circular Arrays

A planar array with the elements positioned in a circular ring creates a circular array. Figure 3-9 presents N isotropic elements spaced on a circular ring with radius R .

The array factor is

$$AF(\theta, \phi) = \sum_{n=1}^N I_n e^{j\beta R [\sin \theta \cos(\phi - \phi_n) - \sin \theta_0 \cos(\phi_0 - \phi_n)]} \quad (3-57)$$

I_n is the amplitude of the excitation and (θ_0, ϕ_0) is the direction where maximum occurs.

A short dipole positioned at the bisector of a corner reflector with angle $\omega_N = \pi/N$ produces $2N - 1$ images that create a circular array. The radiation pattern of this array can be derived from the contribution of the element and its images. The real pattern is in front of the corner.

M circular arrays in concentric rings have an array factor of

$$AF(\theta, \phi) = \sum_{m=1}^M \sum_{n=1}^N I_{mn} e^{j[\beta R_m \sin \theta \cos(\phi - \phi_{mn}) + \alpha_{mn}]} \quad (3-58)$$

$I_{mn} e^{j\alpha_{mn}}$ presents the excitation of the n th element of the m th ring.

A usual concentric ring can come from a corner reflector with a linear array positioned in front of it.

FIGURE 3-8 Three-dimensional patterns for an 8×6 rectangular array with $\alpha_x = \alpha_y = 0$: (a) Uniform arrays with $d_x = d_y = \lambda$; (b) Dolph-Chebyshev arrays with $SLL = -20$ dB and $d_x = d_y = \lambda/2$

FIGURE 3-9 Geometry of a circular array with radius R and N isotropic sources

3.5 THREE DIMENSIONAL AND CONFORMAL ARRAYS

A 3D array (see Figure 3-1) with N elements has an array factor of the form

$$AF(\theta, \phi) = \sum_{n=1}^N I_n e^{j[\alpha_n + \beta r_n [\sin \theta \sin \theta_n \cos(\phi - \phi_n) + \cos \theta \cos \theta_n]]} \quad (3-59)$$

$I_n e^{j\alpha_n}$ is the complex excitation, and (r_n, θ_n, ϕ_n) are the spherical coordinates of the n th element. A *cylindrical array* is a special kind of 3D array. Circular arrays of the same radius with their centers on the same axis create a cylindrical array. A linear array in front of a corner reflector of angle $\omega_N = \pi/N$ with its axis parallel to the edge positioned at its bisector is a virtual cylindrical array. Such an array is an extremely useful 3D array with applications in radio and mobile communications.

Conformity requirements of arrays to a shaped surface create *conformal arrays*. Conformal arrays are used in mobile platforms and in stationary shaped surfaces for specified angles of coverage.

The pattern of a conformal array is given by Eq. 3-1 and Eq. 3-2 because the element pattern and the array factor are inseparable. Surface illumination, polarization, and the pattern of each element have to be taken into account separately. Cylindrical, conical, and parabolic conformal arrays are usual and suitable for missiles and aircrafts. An example of a cylindrical array of microstrip patches and its pattern that has $SLL < -30$ dB and maximum at $\theta_0 = \pi/2$ and $\phi_0 = 0$ are presented in Figure 3-10.

3.6 ARRAY SYNTHESIS TECHNIQUES

Synthesis of an array aims at the approximation of a desired radiation pattern with a given accuracy. Several analytical techniques of narrow-beam and low SLL patterns have been presented previously. Moreover, the mean square error, the orthogonal method, the matrix

FIGURE 3-10 (a) A cylindrical conformal array with rectangular patches in interelement distance 1.16λ ; (b) The pattern for $N = 24$ elements and $SLL < -30$ dB

method, the simplex, the gradient method, the simulated annealing, and the Genetic algorithms are used for the pattern synthesis.

Orthogonal Methods

The orthogonal methods transform the basis of the array factor to an orthogonal basis. The new basis can easily handle the synthesis problem by deriving the excitation of the array. If the geometry of an array has to be found, the orthogonal perturbation method is applied. In this case, the position of the array elements, in an orthogonal manner, is perturbed, and the final geometry is derived by iteration procedure.

The Woodward-Lawson (WL) method is a simple orthogonal technique where an orthogonal set of beams is used.¹ Also, Fourier transform is a method based on the orthogonal components of the array factor.

Woodward-Lawson Method

The Woodward-Lawson (WL) method for discrete arrays can be implemented by superimposing groups of beams of uniform linear arrays. A uniform linear array with N elements of equal distance d/λ creates a beam pattern of the form

$$f_m(\theta) = b_m \frac{\sin(N\psi_m/2)}{N \sin(\psi_m/2)} \quad (3-60)$$

$$\psi_m = \beta d (\cos \theta - \cos \theta_m) \quad (3-61)$$

The superposition of $2M + 1$ terms of the form in Eq. 3-60 gives an array factor that is

$$AF(\theta) = \sum_{m=-M}^M b_m \frac{\sin(N\psi_m/2)}{N \sin(\psi_m/2)} \quad (3-62)$$

Sampling $AF(\theta)$ at the angles

$$\theta_m = \cos^{-1} \left(m \frac{\lambda}{Nd} \right) \quad (3-63)$$

we have

$$b_m = AF(\theta_m) \quad (3-64)$$

The excitation coefficients of a linear array with an array factor of the form of Eq. 3-62 are

$$I_n = \frac{1}{N} \sum_{m=-M}^M AF(\theta_m) e^{-j\beta d_n \cos \theta_m} \quad (3-65)$$

If, instead of a linear array, you have a line source, you can superimpose groups of beams of uniform line sources. In this case, you create a space factor with similar characteristics to the array factor.

A discrete element array can be designed from the line source by sampling the previous distribution. An example for a cosecant-squared power pattern by sampling the appropriate line source will be given next. Figure 3-11 presents the pattern by a line source with $L = 10\lambda$ and the same pattern of a discrete linear array with 20 elements. The excitation of the array is coming from the uniform sampling of the line source.

FIGURE 3-11 Cosecant-squared power pattern of a line source with $L = 10\lambda$ and of a discrete linear array with 20 elements. The array is coming from the uniform sampling of the line source.

Fourier and Orthogonal Method

A nonuniformly spaced linear array (see Figure 3-3) gives an array factor of the form

$$AF_d(u) = \sum_{n=1}^N I_n e^{jx_n u} \quad (3-66)$$

$$u = \pi \cos \theta, \quad x_n = \frac{d_n}{\lambda/2} \quad (3-67)$$

In general, the expansion functions $e^{jx_n u}$ are not orthogonal because the inner product $K_{in} \neq 0$:

$$K_{in} = \int_{-\pi}^{\pi} e^{j(x_i - x_n)u} du = \frac{\sin(x_i - x_n)\pi}{(x_i - x_n)\pi} \neq 0 \quad (3-68)$$

$AF_d(u)$ can be expressed in an orthogonal basis $\{\Psi_n(u)\}$ by the Gram-Schmidt procedure,³ which is

$$\Psi_n(u) = \sum_{i=1}^n c_i^{(n)} e^{jx_i u} \quad (3-69)$$

$$AF_d(u) = \sum_{n=1}^N B_n \Psi_n(u) \quad (3-70)$$

From Eq. 3-70, you then have

$$B_n = \int_{-\pi}^{\pi} AF_d(u) \cdot \Psi_n^*(u) du \quad (3-71)$$

$\Psi_n^*(u)$ is the conjugate of $\Psi_n(u)$. Combining Eq. 3-66 to Eq. 3-70, you find that

$$I_n = \sum_{i=n}^N c_n^{(i)} B_i \quad (3-72)$$

Equation 3-72 shows that the excitation of the elements can be derived by using the orthogonal method. If the elements of the array are uniformly spaced with $K_{in} = 0$, then the previous method is reduced to the Fourier. Several applications that explain the orthogonal procedure can be found in the literature.³

An example of a 13-element array with 0.87λ spacing and a constant beam between 87° and 93° is given here. Figure 3-12 presents this pattern. The orthogonal method can be used for 2D and 3D arrays with a similar formulation. Also, with modification, it can take into account the coupling between the elements.

Orthogonal Perturbation Method

The orthogonal perturbation method combines an iterative technique with the orthogonal method. A nonuniformly spaced linear array has an array factor of the form

$$AF_0(\theta) = \sum_{i=1}^N I_i e^{j\beta d_i \cos \theta} = \sum_{i=1}^N I_i \Phi_i(\theta) \quad (3-73)$$

A perturbation of the position d_i of each element such that $\beta(\delta d_i) \ll 1$ transforms the array factor to

$$AF_1(\theta) \cong \sum_{i=1}^N [1 + j\beta(\delta d_i) \cos \theta] I_i e^{j\beta d_i \cos \theta} \quad (3-74)$$

From Eq. 3-73 and Eq. 3-74 you can derive

$$F(\theta) = \frac{AF_1(\theta) - AF_0(\theta)}{\cos \theta} = \sum_{i=1}^N A_i \Phi_i(\theta) \quad (3-75)$$

$$A_i = j\beta(\delta d_i) I_i \quad (3-76)$$

FIGURE 3-12 Beam from 87° to 93° by the orthogonal method of an array with $N=13$ and $d/\lambda = 0.87\lambda$

$F(\theta)$ is similar to $AF_0(\theta)$, and the orthogonal method to establish an orthogonal basis $\{\Psi_i(\theta)\}$ can be applied for both of the previous equations. For the new basis, you have

$$AF_0(\theta) = \sum_{i=1}^N B_i^0 \Psi_i(\theta), F(\theta) = \sum_{i=1}^N B_i \Psi_i(\theta) \quad (3-77)$$

$$B_i^0 = \langle AF_0(\theta), \Psi_i(\theta) \rangle, B_i = \langle F(\theta), \Psi_i(\theta) \rangle \quad (3-78)$$

I_i and A_i are finally found.

$$I_i = \sum_{j=1}^N B_j^0 c_i^{(j)}, A_i = \sum_{j=1}^N B_j c_i^{(j)} = j\beta(\delta d_i) I_i \quad (3-79)$$

A significant change of the initial pattern $AF_0(\theta)$ can be obtained by using the procedure iteratively. The final positions of the array elements are found in the last iteration, where the desired approximation of the pattern is obtained. A Chebyshev pattern $T_{12}(x)$ with $SLL = -25$ dB and $HPBW = 9.2^\circ$ for a 13-element array and the amplitudes are shown in Figure 3-13 and in Table 3-3.

Synthesis as an Optimization Procedure

Synthesis of an antenna array can be characterized as a nonlinear optimization procedure. With this procedure, one or more convenient real functions that take their optimum values are constructed. These functions fit several antenna characteristics. Such characteristics are the radiation pattern, the impedance, an index, the antenna coupling, the excitation, the geometry, the size, the loadings, and the current of the antenna elements.

Optimization methods make use of the values of the optimization function or look at the gradient of this function. Optimization functions, in some cases, are not explicit functions, but they are computed numerically.

Except for the previous procedures, there are methods based on random searches. These methods make use of a random number generator that helps to determine successive points. Moreover, the simulated annealing and the Genetic algorithms are global optimizers that have found applications in antenna synthesis.

FIGURE 3-13 A $T_{12}(x)$ pattern with $SLL = -25$ dB and $HPBW = 9.2^\circ$ taken from an array with 13 elements

TABLE 3-3 Amplitudes and Positions of the Elements of the Array with the Pattern in Figure 3-13

Position (λ)	± 3.006	± 2.436	± 2.065	± 1.525	± 0.952	± 0.467	0.000

Optimization of an Index In synthesis problems, the general purpose for a given array geometry is to derive the excitations without or under certain constraints. Most of the procedures that are commonly used suppose the existence of passive feed networks. These networks consist of suitable power combiners that concentrate all the element ports into one port. Modern arrays in corporate feed networks make use of *digital beamforming*. The pattern information is first digitized for each element and is then added together in a digital processor. The whole system, known as a *digital corporate feed*, produces the same pattern with the classical corporate structure. The element excitation at the feeder output can be found by pattern optimization. Casting certain array indices into an expression that is the ratio of Hermitian quadratic forms creates the procedure. An antenna index, I , such as directivity, gain, and so on, can be written as

$$I = \frac{[\tilde{u}]^* [A] [u]}{[\tilde{u}]^* [M] [u]} \quad (3-80)$$

$[\tilde{u}]^* = [u_1 \ u_2 \ \dots \ u_N]^*$ is the conjugate transpose of $[u]$. With $[u]$, you can represent the current or the voltage excitation vector of the array:

$$\left. \begin{aligned} [A] &= [\alpha_{ij}] \\ [M] &= [m_{ij}] \end{aligned} \right\} \quad (3-81)$$

$[A]$ and $[M]$ are Hermitian $N \times N$ square matrices and $[M]$ is a positive definite matrix. An optimization case is created by maximizing the index I subject to constrain another index I_1 , which equals a specified value.

$$I_1 = \frac{[\tilde{u}]^* [M_2] [u]}{[\tilde{u}]^* [M_3] [u]} = \gamma \quad (3-82)$$

Using the Lagrange multiplier and by setting the quantity L ,

$$L = \frac{[\tilde{u}]^* [A] [u]}{[\tilde{u}]^* [M] [u]} + \lambda \left\{ \frac{[\tilde{u}]^* [M_2] [u]}{[\tilde{u}]^* [M_3] [u]} - \gamma \right\} \quad (3-83)$$

stationary with respect to $[u]$ and λ you have

$$[u] = q [K]^{-1} [\tilde{B}]^* \quad (3-84)$$

q is a constant, and matrix $[K]$ is

$$[K] = [M] + p \{ \gamma [M_3] - [M_2] \} \quad (3-85)$$

The parameter p is found from the constraint equation (Eq. 3-84). You can find more details in the literature.¹³ If the parameter p is zero, optimization of I is without constraints.

Optimization by Simplex, Gradient, Simulated Annealing Methods, and Genetic Algorithms (GAs) The simplex method calculates the values of the optimization function at the vertices of a simplex. The term *simplex* means a body in multidimensional space. Based on the values of the optimization function, a smaller simplex is chosen within which an optimum should be created. The optimum depends on the initial simplex.¹⁴

The gradient or steepest-descent methods choose a starting point in the direction where the optimization function decreases most rapidly. By adopting a new point in that direction at a desired distance and then repeating the process, you achieve a minimum of the optimization function. Note, however, that the minimum is not always the global function. From an antenna engineering point-of-view, a suite solution is, in many cases, enough.

Simulated annealing combines local search with Monte Carlo techniques in analogy to the cooling processes in thermodynamics.¹⁵ *Annealing* refers to a process used to reveal the low temperature state of some material. The time spent at each temperature must be of sufficient length to allow thermal equilibrium to be realized. *Simulated annealing* means to simulate the annealing process using a Monte Carlo method where the global minimum of the objective function represents the low energy configuration.

In the simulated annealing process, parallelization techniques with the use of multiple CPUs are useful. Simulated annealing methods have been used in antenna design.¹⁶ The idea is to randomly change the array configuration (element position, amplitude, and phase). All or some of the antenna parameters are perturbed during the annealing process. The objective function can be the approximation of a desired pattern with another criterion in the sidelobe level and the antenna impedance in one or more frequencies.

Genetic algorithms are global optimizers in contrast to the local optimizer methods such as simplex and conjugate gradient methods. Genetic algorithms (GAs) can encode and improve complex structures using simple transformations. They are suitable for constrained optimization problems and are based on Darwin's principle¹⁷: survival of the fittest. The function to be optimized represents fitness.

The main concepts in GAs are selection, crossover, and mutation. Selection is the process of selecting the individuals to be mated. Selection can follow both probabilistic and deterministic rules based on the fitness of each individual. Crossover occurs with a probability P_c (usually 0.6–0.9) and involves the combination of the genetic information of the two parents. The crossover operator creates two new individuals with genetic characteristics from both parents. There is a probability of mutation for each new individual P_m (usually between 0.01–0.05). Mutation is a way of expanding the solution space to new unexplored domains.

GAs, in many cases due to algorithm-inherited complexity, require long computational times. To increase efficiency, an evolutionary algorithm based on the bird fly has been used recently. This algorithm is called *Particle Swarm Optimization (PSO)*.¹⁸ PSO is easy to implement and is used for single- and multi-objective optimization.

3.7 SMART ANTENNAS

Smart antennas are antenna arrays that are combined with signal processing in space and real time. They can be used in cellular and satellite mobile communications. Smart antennas increase spectrum efficiency and channel capacity. By multiplying beamsteering and electronically compensating distortion, they can extend the range of coverage. Smart antennas can provide a certain channel in a certain direction. They can also reduce propagation problems (multipath fading, co-channel interference, delay spread) and improve communication indices (bit error rate (BER) and outage probability, for example).

Smart antennas are characterized as adaptive arrays, intelligent antennas, spatial processing, digital beamforming antennas, among others.¹⁹ Two types of smart systems are available: *switchedbeam* and the *adaptive system*. The switched-beam antenna divides the communication area into micro-sectors. Each micro-sector contains a predetermined fixed-beam pattern. The adaptive systems dynamically alter the patterns to optimize communications performance. Adaptive array theory is based on optimization methods and on real-time response in a transient environment.

There are many special issues, books and specialized research papers in the area of smart antennas.

Smart antennas can be analyzed for different network topologies and mobility scenarios. Their geometries are realized with the appropriate feed networks and the algorithms for fast beamforming and direction of arrival. The cost of smart antennas continues to be the most critical issue.

3.8 ELEMENT PATTERN AND MUTUAL COUPLING

In the analysis and synthesis of antenna arrays, it was assumed that the characteristics of the elements were proportional to their excitations and that they were the same for similar elements and unchanged as the array was scanned. Actually, all of the currents and fields differ in magnitude, phase, and distribution from element to element. This happens because mutual coupling is involved in the behavior of the elements. In the literature, you will find several examples of a different pattern of an isolated element and the one in an array.^{3,7} An antenna array that shows more visually the importance of mutual coupling is the Yagi-Uda. In the Yagi-Uda array, due to the coupling, one of the elements (feeder) is enough to excite the parasitic ones (reflector, directors). Yagi-Uda produces easily directive patterns. Figure 3-14 presents the pattern of a four-element Yagi-Uda array.

In antenna array synthesis, the required distributions of the elements have to be derived. Different methods depend on the problem, such as the boundary value; the transmission line and the Poynting vector method are discussed in the literature. In the late 1960s, the integral

FIGURE 3-14 H-pattern of a four-dipole Yagi-Uda array. The distance between the elements is $d/\lambda = 0.30$, and the lengths are as follows: reflector = 0.50λ , feeder = 0.465λ , directors = 0.45λ , and dipole radius = 0.001λ .

equations with suitable numerical techniques, as the Method of Moments (MoM)²⁰ were given. The MoM reduces the integral equations to a system of simultaneous linear algebraic equations in terms of the unknown current or aperture distribution. There are computer codes, such as NEC and MININEC, used for evaluating the radiation characteristics of antennas.

Obviously, an antenna array needs the appropriate feed network to operate. There are several feeds, but the most usual are the series and the shunt feeds. In feed networks, impedance matching and the isolation between the outputs are critical functions. In the literature, you can find extended analysis of feed systems.^{1,7}

4.1 INTRODUCTION

Since the publication of the first edition of this handbook several sections in the original chapter on linear antennas have become outdated and have been deleted in this edition. The availability of computer programs¹ for finding the impedance and other characteristics of antennas, particularly linear antennas, makes parametric tabulation of limited use. Only some essential formulas and design data are therefore included in this chapter.

For the entire subject of linear antennas, the book by R. W. P. King² remains authoritative. Another book³ by the same author on the tables of antenna characteristics contains the most comprehensive data on the characteristics of cylindrical antennas. Calculations on circular-loop antennas and some simple arrays are also found there.

A section on the effective height of antennas is included in this chapter. The use of this parameter in describing the transmitting and receiving characteristics of linear antennas and other simple structures is discussed in detail. In addition, material on the general formulation of receiving antennas is included so that engineers can apply the formulation for design purposes or for estimation of the coupling effect between elements made up of both linear and other types of antennas.

Antennas in lossy media are of great current interest. Unfortunately, the subject cannot be covered in this chapter because of limited space. The book by King and Smith⁴ on antennas in matter can be consulted for this subject, particularly for linear antennas embedded in a lossy medium.

4.2 CYLINDRICAL DIPOLES

Impedance as a Function of Length and Diameter

The impedance characteristics of cylindrical antennas have been investigated by many writers. Theoretical work has mainly been confined to relatively thin antennas (length-to-diameter ratio greater than 15), and the effect of the junction connecting the antenna proper and the transmission line is usually not considered. Among various theories, the induced-emf method⁵ of computing the impedance of a cylindrical antenna based upon a sinusoidal distribution is still found to be very useful. The formula derived from this method is extremely simple. It is, however, valid only when the half length of a center-driven antenna is not much longer than a quarter wavelength. In practice, this is the most useful range. To eliminate unnecessary computations, the formula has been reduced to the following form:⁶

$$Z_i = R(k\ell) - j \left[120 \left(\ln \frac{\ell}{a} - 1 \right) \cot k\ell - X(k\ell) \right] \quad (4-1)$$

where

Z_i = input impedance, Ω , of a center-driven cylindrical antenna of total length 2ℓ and of radius a

$k\ell = 2\pi(\ell/\lambda)$ = electrical length, corresponding to ℓ , measured in radians

The functions $R(k\ell)$ and $X(k\ell)$ are tabulated in Table 4-1 and plotted in Figure 4-1 for the range $k\ell \leq \pi/2$. For calculation purposes, these two functions can be approximated to within 0.5Ω by the following simple third-order polynomials:

$$R(k\ell) = -0.4787 + 7.3246k\ell + 0.3963(k\ell)^2 + 15.6131(k\ell)^3$$

$$X(k\ell) = -0.4456 + 17.0082k\ell - 8.6793(k\ell)^2 + 9.6031(k\ell)^3$$

TABLE 4-1 Functions $R(k\ell)$ and $X(k\ell)$ Contained in the Formula of the Input Impedance of a Center-Driven Cylindrical Antenna

$k\ell$	$R(k\ell)$	$X(k\ell)$	$k\ell$	$R(k\ell)$	$X(k\ell)$
0	0	0	0.9	18.16	15.01
0.1	0.1506	1.010	1.0	23.07	17.59
0.2	0.7980	2.302	1.1	28.83	20.54
0.3	1.821	3.818	1.2	35.60	23.93
0.4	3.264	5.584	1.3	43.55	27.88
0.5	5.171	7.141	1.4	52.92	32.20
0.6	7.563	8.829	1.5	64.01	38.00
0.7	10.48	10.68	$\pi/2$	73.12	42.46
0.8	13.99	12.73			

When the length of the antenna is short compared with a wavelength but still large compared with its radius, the same formula reduces to

$$(Z_i)_{\text{short}} = 20(k\ell)^2 - j120(k\ell)^{-1} \left(\ln \frac{\ell}{a} - 1 \right) \quad (4-2)$$

For antennas of half length greater than a quarter wavelength, a number of refined theories provide formulas for the computation of the impedance function. None of them, however, is simple enough to be included here. As far as numerical computation is concerned, Schelkunoff's method⁷ is relatively simpler than Hallén's.² It should be emphasized that all these theories are formulated by using an idealized model in which the terminal condition is not considered.

FIGURE 4-1 The functions $R(k\ell)$ and $X(k\ell)$

FIGURE 4-2 Driving an antenna by transmission lines

In practice, the antenna is always fed by a transmission line. The complete system may have the appearances shown in Figure 4-2. The effective terminal impedance of the line (often referred to as the *antenna impedance*) then depends not only upon the length and the diameter of the antenna but also upon the terminal condition. In cases *a* and *b*, the impedance would also be a function of the size of the ground plane. For a given terminal condition the variation of the impedance of a cylindrical antenna as a function of the length and the diameter of the antenna is best shown in the experimental work of Brown and Woodward.⁸ The data cover a wide range of values of the length-to-diameter ratio. Two useful sets of curves are reproduced in Figures 4-3 and 4-4. The impedance refers to a cylindrical antenna

FIGURE 4-3 Antenna resistance versus antenna length A when a constant ratio of length to diameter A/D is maintained. The length and diameter are held constant while the frequency is changed.

FIGURE 4-4 Reactance curves corresponding to the resistance curves of Figure 4-3

driven by a coaxial line through a large circular ground plane placed on the surface of the earth. The arrangement is similar to the one sketched in Figure 4-2a. The length and diameter of the antenna are measured in degrees; i.e., a length of one wavelength is equivalent to 360° . If the effects due to the terminal condition and finite-size ground plane are neglected, the impedance would correspond to one-half of the impedance of a center-driven antenna (Figure 4-2c). In using these data for design purposes, you must take into consideration the actual terminal condition as compared with the condition specified by these two authors. In particular, the maximum value of the resistance and the resonant length of the antenna may change considerably if the base capacitance is excessive.

Effect of Terminal Conditions

Many authors have attempted to determine the equivalent-circuit elements corresponding to different terminal conditions. Schelkunoff and Friis⁹ have introduced the concepts of *base capacitance* and *near-base capacitance* to explain the shift of the impedance curve as the terminal condition is changed. Similar interpretations have been given by King¹⁰ for a cylindrical antenna driven by a two-wire line or by a coaxial line and by Whinnery¹¹ for a biconical antenna driven by coaxial line. The importance of the terminal condition in affecting the input impedance of the antenna is shown in Figures 4-5 and 4-6. They are again reproduced from Brown and Woodward's paper. Because of the large variation of the effective terminal impedance of the line with changes in the geometry of the terminal junction, you must be cautious when using the theoretical results based upon isolated antennas. For junctions possessing simple geometry, the static method of Schelkunoff and Friis, King, and Whinnery can be applied to estimate the shunt capacitance of the junction.

FIGURE 4-5 Resistance as a function of antenna length A . The diameter D is 20.6° . Curve A : The arrangement shown in Figure 4-2*b*. Curve B : The arrangement of Figure 4-2*a* with the diameter of the outer conductor equal to 74° . The characteristic impedance of the transmission line is $77.0\ \Omega$. Curve C : The outer-conductor diameter is 49.5° , and the transmission line has a characteristic impedance of $52.5\ \Omega$. Curve D : The diameter of the outer conductor is 33° . The characteristic impedance is $28.3\ \Omega$. Curve E : This curve was obtained by tuning out the base reactance with an inductive reactance of $65.0\ \Omega$.

The latter then can be combined with the impedance of the antenna proper to evaluate the resultant impedance. For intricate junctions, accurate information can be obtained only by direct measurement.

Equivalent Radius of Noncircular Cross Sections

As far as the impedance characteristics and radiation pattern are concerned, a thin cylindrical antenna with a noncircular cross section behaves like a circular cylindrical antenna

FIGURE 4-6 Reactance curves corresponding to the resistance curves of Figure 4-5

FIGURE 4-7 Equivalent radius a_{eq} of a rectangle as a function of the ratio of thickness t to width s

with an equivalent radius. In stating this characteristic, the terminal effect is, of course, not considered. The equivalent radius of many simply shaped cross sections can be found by the method of conformal mapping.¹² For an elliptical cross section, the following simple relation exists:

$$a_{eq} = \frac{1}{2}(a + b) \quad (4-3)$$

where

a = major half-axis of ellipse

b = minor half-axis of ellipse

For a rectangular cross section, the result is plotted in Figure 4-7. In the case of a strip, Eq. 4-3 and Figure 4-7 give the identical result of an equivalent radius equal to half the strip width. When the cross section has the form of a regular polygon, the result is tabulated in Table 4-2. The equivalent radius of two parallel cylinders of radius ρ_1 and ρ_2 separated by a distance d between the centers is given by¹³

$$\ln \rho_e = \frac{1}{(\rho_1 + \rho_2)^2} (\rho_1^2 \ln \rho_1 + \rho_2^2 \ln \rho_2 + 2\rho_1 \rho_2 \ln d) \quad (4-4)$$

Formulas for the equivalent radius of three cylinders and an angle strip are found in *Yagi-Uda Antenna* by S. Uda and Y. Mushiake.¹³

TABLE 4-2 Equivalent Radius of a Regular Polygon

Patterns as a Function of Length and Diameter

In this subsection the radiation pattern of only center-driven cylindrical antennas is discussed. For base-driven antennas, the patterns depend very much upon the size of the ground plane. The subject will be discussed in Section 4.8.

The radiation pattern of a center-driven cylindrical antenna in general depends upon its length and thickness. The terminal condition that plays an important role in determining its impedance has a negligible effect on the pattern. For thin antennas, the calculated pattern obtained by assuming a sinusoidal current distribution is a good approximation of the actual pattern. Thus, with an assumed current distribution of the form

$$I(z) = I_0 \sin k(\ell - |z|) \quad +\ell \geq z \geq -\ell \quad (4-5)$$

the radiation field, expressed in a spherical coordinate system, is given by

$$E_\theta = \frac{j\eta I_0 e^{jkR}}{2\pi R} \left[\frac{\cos(k\ell \cos\theta) - \cos k\ell}{\sin\theta} \right] \quad (4-6)$$

where

$$\eta = (\mu/\epsilon)^{1/2} = 120\pi \Omega$$

θ = polar angle measured from axis of dipole, or z axis

The field pattern is obtained by evaluating the *magnitude* of the term contained in the brackets of Eq. 4-6. Some of the common patterns are shown in Figure 4-8. Comparing those patterns with the actual patterns of a thin cylindrical antenna obtained by measurement, reveals that the theoretical patterns based upon a sinusoidal current distribution do not produce the following characteristics found in actual measurements:

- The nulls between the lobes, except the *natural null* in the direction of the axis, are actually not zero.
- The phase of the field varies continuously from lobe to lobe instead of having a sudden jump of 180° between the adjacent lobes.
- The actual patterns vary slightly as a function of the radius of the antenna instead of being independent of the thickness.

Depending upon the particular applications, some of the fine details may require special attention. In most cases, the idealized patterns based upon a sinusoidal current distribution give us sufficient information for design purposes.

FIGURE 4-8 Radiation patterns of center-driven dipoles if sinusoidal current distribution is assumed

When the half length ℓ of the antenna is less than about one-tenth wavelength, Eq. 4-6 is well approximated by

$$E_{\theta} = \frac{j\eta I_0 (k\ell)^2 e^{jkR}}{4\pi R} \sin \theta \quad (4-7)$$

The figure-eight pattern resulting from the plot of the sine function is a characteristic not only of short cylindrical antennas but also of all small dipole-type antennas. Equations 4-6 and 4-7 are also commonly used to evaluate the directivity of linear antennas. The directivity is defined as

$$D = \frac{\text{maximum radiation intensity}}{\text{average radiation intensity}} \quad (4-8)$$

For a short dipole, D is equal to 1.5. The directivity of a half-wave dipole ($\ell = \lambda/4$) is equal to 1.64. The half-wave dipole is often used as a reference antenna to describe the gain of more directive antennas, particularly arrays made of dipoles.

4.3 BICONICAL DIPOLES

Impedance as a Function of Length and Cone Angle

When the angles of a symmetrical biconical antenna (Figure 4-9) are small, the input impedance of the antenna can be calculated using Schelkunoff's formula.¹⁴ Some sample curves are shown in Figure 4-10. While the biconical antenna is an excellent theoretical model for studying the essential property of a dipole-type antenna, small-angle biconical antennas are seldom used in practice. Wide-angle biconical antennas or their derived types such as discons, however, are frequently used as broadband antennas. The broadband impedance characteristics occur when the angle of the cones, θ_0 of Figure 4-9, lies between 30 and 60°.

FIGURE 4-9 A biconical dipole

The exact value of θ_0 is not critical. Usually it is chosen so that the characteristic impedance of the biconical dipole matches as closely as possible the characteristic impedance of the line that feeds the antenna. The characteristic impedance of a biconical dipole as a function of the angle is plotted in Figure 4-11. For a conical monopole driven against an infinitely large ground plane, the characteristic impedance and the input impedance of the antenna are equal to half of the corresponding values of a dipole. Several formulas¹⁵ are available for computing the input impedance of wide-angle biconical antennas. Actual computation has been confined to a very few specific values of θ_0 .^{16,17} More complete information is available from the experimental data obtained by Brown and Woodward.¹⁸ Two curves are reproduced in Figures 4-12 and 4-13. The case corresponding to $\alpha = 0^\circ$ represents a cylindrical antenna having a diameter of 2.5 electrical degrees at a frequency of 500 MHz, since the feed point was kept fixed at that diameter.

FIGURE 4-10a Input impedance of small-angle biconical antennas (resistance)

Patterns of the Biconical Dipole

The radiation patterns of biconical dipoles have been investigated theoretically by Papas and King.¹⁹ Figure 4-14 shows the patterns of a 60°-flare-angle ($\theta_0 = 30^\circ$) conical dipole for various values of ka , where $k = 2\pi/\lambda$ and a = half length of the dipole, which is the same as the ℓ used in Figure 4-9. Similar curves corresponding to different values of the flare angle have been obtained experimentally by Brown and Woodward.¹⁸

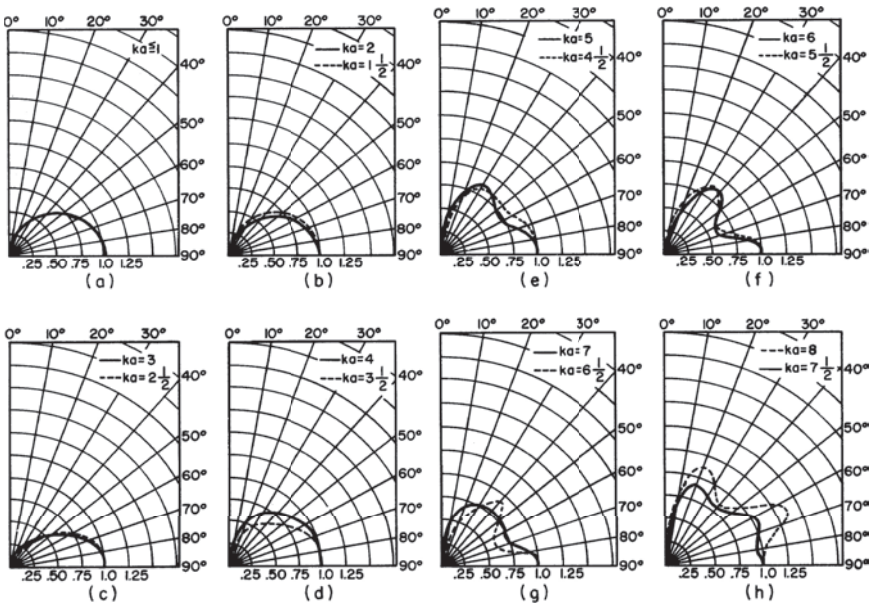

FIGURE 4-14 Plots of the absolute values of the far-zone electric field as a function of the zenithal angle θ for various values of ka and with a flare angle equal to 60° ($\theta_0 = 30^\circ$)

4.4 FOLDED DIPOLES

Equivalent Circuit of a Folded Dipole

A folded dipole is formed by joining two cylindrical dipoles at the ends and driving them by a pair of transmission lines at the center of one arm, as shown in Figure 4-15. The diameters of the two arms can be either identical or different. A simple analysis, based upon a quasi-static approach, of the operation of a folded dipole of arbitrary dimensions has been given by Uda and Mushiaki.¹³ According to their method, the excitation of a folded dipole can be considered as a superposition of two modes, as shown in Figure 4-16. The impedance of the

FIGURE 4-15 Folded dipole

FIGURE 4-16 Decomposition of the folded dipole into two fundamental modes

symmetrical mode, characterized by two equal driving voltages, can be calculated by making use of the equivalent radius of two conductors as discussed in Section 4.2. The equivalence is shown in Figure 4-17. The impedance function Z_r is therefore the same as the impedance of a cylindrical dipole with an equivalent radius ρ_e given by

FIGURE 4-17 The equivalent representation of the symmetrical mode in computing Z_r

$$\ln \rho_e = \ln \rho_1 + \frac{1}{(1+\mu)^2} (\mu^2 \ln \mu + 2\mu \ln v) \quad (4-9)$$

where the various parameters are explained in Figure 4-16. The impedance of the asymmetrical mode, characterized by equal and opposite currents on the two arms, is the same as the shorted section of transmission line of length equal to ℓ ; that is,

$$Z_f = \frac{(1+a)V}{2I_f} = jZ_0 \tan k\ell \quad (4-10)$$

where Z_0 is the characteristic impedance of the two-wire line. Expressed in terms of Z_r and Z_f , the input impedance of a folded dipole is given by

$$Z = \frac{V_i}{I_i} = \frac{(1+a)V}{I_r + I_f} = \frac{2(1+a)^2 Z_r Z_f}{(1+a)^2 Z_r + 2Z_f} \quad (4-11)$$

An equivalent circuit based upon Eq. 4-11 is shown in Figure 4-18. For a folded dipole of length ℓ equal to $\lambda/4$, Z_f is very large compared with $(1+a)^2 Z_r$; hence

$$Z_{\lambda/4} = (1+a)^2 Z_r \quad (4-12)$$

Impedance Transformation as a Function of the Ratio of Conductor Sizes

The step-up impedance ratio $(1+a)^2$ as a function of μ and v has been calculated by Mushiake.²⁰ The diagram is reproduced in Figure 4-19 by using the formula for a given in

FIGURE 4-18 Equivalent circuit of a folded dipole

FIGURE 4-19 Step-up transformation chart for a folded dipole

Figure 4-16. When ρ_1 and ρ_2 are small compared with d , the value of a is given to a good approximation by

$$a = \frac{\ln(d/\rho_1)}{\ln(d/\rho_2)} \quad (4-13)$$

This formula was first derived by Guertler.²¹

Other presentations²² of the transformation ratio $(1 + a)^2$ in a logarithmic scale as a function of ρ_2/ρ_1 and d/ρ_1 are given in Figures 4-20 and 4-21.

4.5 SLEEVE DIPOLES

Equivalent Circuit of a Sleeve Dipole

The geometrical shape of a sleeve antenna, or a sleeve monopole, is shown in Figure 4-22a. If the image of the structure is included, then you have a sleeve dipole, as shown in Figure 4-22b. A sleeve dipole can therefore be considered as a doubly fed antenna in which the current is a relative maximum at the center of the dipole or at the base of the monopole. Antiresonances of the antenna impedance function take place when S is approximately equal to an odd multiple of a quarter wavelength or L is a multiple of a half wave. A special case of interest is that in which $L + S$ is equal to a quarter wavelength. Then the current distribution along the structure is approximately cosinusoidal. At resonance, the input resistance of the sleeve monopole or the sleeve dipole is approximately given by

$$R_s = R \left(\csc \frac{2\pi L}{\lambda} \right)^2 \quad (4-14)$$

where R denotes either the input resistance of a resonant quarter-wave monopole or that of a half-wave dipole. The sleeve in this case plays the role of an impedance transformer.

Wong and King²³ have shown experimentally that properly designed open-sleeve dipoles exhibit a broadband voltage-standing-wave-ratio (VSWR) response and unidirectional

FIGURE 4-20 ρ_2/ρ_1 versus d/ρ_1 for various impedance transformation ratios (after Hansen²² © IEEE 1982)

radiation patterns over nearly an octave bandwidth when placed above a reflector. Figure 4-23 shows the VSWR response of open-sleeve dipoles for various dipole and sleeve diameters. Figure 4-24 shows the same response with sleeve spacing as the parameter.

Open Folded Sleeve Monopole

The work of Uda and Mushiaki¹³ on folded dipoles can be extended to include a load at the unexcited arm, as shown schematically in Figure 4-25. The impedance of the loaded dipole is given by

$$Z_i = \frac{(Z_a + Z_L)Z_s + \left(\frac{a}{1+a}\right)^2 Z_L Z_a}{Z_s + Z_L + \frac{1}{(1+a)^2} Z_a} \quad (4-15)$$

FIGURE 4-21 Impedance transformation ratio versus d/ρ_1 for various values of ρ_2/ρ_1 (after Hansen²² © IEEE 1982)

FIGURE 4-22 The sleeve antenna

FIGURE 4-23 VSWR response of open-sleeve dipoles for various dipole and sleeve diameters

where

$$Z_a = jZ_c \tan \frac{2\pi \ell}{\lambda}$$

$$Z_c = \frac{Z_0}{2\pi} \left\{ \cos h^{-1} \left[\frac{1}{2v} (1 + \gamma^2 - \mu^2) \right] + \cos h^{-1} \left[\frac{1}{2v\mu} (-1 + \gamma^2 + \mu^2) \right] \right\}$$

Z_s = input impedance of the folded dipole when it is driven simultaneously by a common voltage at the base. It is approximately equal to that of a dipole with an equivalent radius ρ_e given by Eq. 4-4.

The parameter a in Eq. 4-15 and the parameters v and μ in the expression for the characteristic impedance Z_c of a transmission line made of wires of unequal radius are the same as those defined for Figure 4-16.

FIGURE 4-24 VSWR for a 3/4-in- (19-mm-) diameter open-sleeve dipole with sleeve spacing as the parameter

FIGURE 4-25 Loaded folded dipole and monopole

In the special case in which Z_L approaches infinity, Eq. 4-15 reduces to

$$Z_i = Z_s + \left(\frac{a}{1+a} \right)^2 Z_a \quad (4-16)$$

The structure then corresponds to an open folded dipole or monopole. Josephson²⁴ studied this structure both theoretically and experimentally. However, his analysis is correct only if the wires are of the same size. A sleeve version of an open folded monopole was also investigated by Josephson. The two structures are shown in Figures 4-26 and 4-27.

The open folded monopole with a displaced feed point is equivalent to a folded sleeve monopole. The input resistance at resonance of the open folded sleeve monopole is given approximately by

$$R_x = R_0 \left(\sin \frac{4\pi s}{\lambda} \right)^2 \bigg/ \left(\sin \frac{2\pi x}{\lambda} \right)^2 \quad (4-17)$$

where R_0 denotes the resonant input resistance of the open folded monopole and R_x is the input resistance of the folded sleeve monopole. The precise value of R_0 depends on the radius of the wires and their separation. A typical value is about 10 Ω . The open folded sleeve monopoles made of arms with different sizes are useful models in designing aircraft trail antennas or fin-type antennas on vehicles as illustrated by Josephson.

FIGURE 4-26 Open folded monopole

FIGURE 4-27 Open folded monopole with a displaced feed point

4.6 EFFECTIVE HEIGHT OF ANTENNAS

General Formula and Its Role in the Theory of Transmitting and Receiving Antennas

The radiation of any antenna can always be written in the form

$$\mathbf{E} = \frac{-jkZ_0 I_i e^{-jkR}}{4\pi R} \mathbf{h} \quad (4-18)$$

where

$$Z_0 = (\mu_0 / \epsilon_0)^{1/2}$$

$$k = 2\pi / \lambda$$

\mathbf{h} = effective height of antenna

I_i = input current to antenna

The effective height of an antenna was originally introduced by Sinclair.²⁵ It is related to the radiation vector defined by Schelkunoff to characterize the radiation field of an antenna, i.e.,

$$\mathbf{N}_t = I_i \mathbf{h} \quad (4-19)$$

where \mathbf{N}_t denotes the transversal part of Schelkunoff's radiation vector. The effective height is a very useful parameter in antenna engineering. For example, the open-circuit voltage of a receiving antenna can be expressed as

$$V_{\text{op}} = \mathbf{E}_i \cdot \mathbf{h} \quad (4-20)$$

where \mathbf{E}_i denotes the incident electric field. It is also an important parameter involved in the polarization-matching factor of a receiving antenna. In the theory of receiving antennas, the receiving cross section or the effective aperture is defined by²⁶

$$A = \frac{\lambda^2}{4\pi} Dpq \quad (4-21)$$

where

λ = operating wavelength

D = directivity of antenna

p = polarization-matching factor

$$= \frac{|\mathbf{h} \cdot \mathbf{E}_i|^2}{|\mathbf{h}|^2 |\mathbf{E}_i|^2}$$

q = impedance-matching factor

$$= 1 - \left| \frac{Z_L - Z_i^*}{Z_L + Z_i} \right|^2$$

Z_i = input impedance of antenna

Z_L = load impedance

The polarization-matching factor again involves the effective-height function. The effective-height function of a center-driven short dipole, if a linear current distribution along the dipole is assumed, is given by

$$\mathbf{h} = -\ell \sin \theta \hat{\theta} \quad (4-22)$$

where ℓ denotes the half length of the dipole that is assumed to be pointed in the vertical direction and θ denotes the polar angle measured between the axis of the dipole and the direction of observation or the direction of radiation. For a linearly polarized incident field making a skew angle α with the axis of the dipole, the polarization-matching factor is given by

$$p = \cos^2 \alpha \quad (4-23)$$

The effective-height functions for other simple antenna elements are listed below:

Antenna Type	Effective Height
Short dipole of length 2ℓ	$-\ell \sin \theta \hat{\theta}$
Half-wave dipole	$-\frac{\lambda}{\pi} \frac{\cos\left(\frac{\pi}{2} \cos \theta\right)}{\sin \theta} \hat{\theta}$
Small loop of radius a pointed in the z direction	$j \frac{2\pi^2 a^2}{\lambda} \sin \theta \hat{\phi}$
Half-wave folded dipole	$-\frac{2\lambda}{\pi} \frac{\cos\left(\frac{\pi}{2} \cos \theta\right)}{\sin \theta} \hat{\theta}$

4.7 COUPLED ANTENNAS

Circuit Relationships of Radiating Systems

When several antennas are coupled to each other, the input voltage and input currents to the antennas follow the same relationship as ordinary coupled circuits.²⁷ For a system of n antennas, the relationships are

$$V_i = \sum_{j=1}^n Z_{ij} I_j \quad i = 1, 2, \dots, n \quad (4-24)$$

where Z_{ii} is called the self-impedance of antenna i and Z_{ij} or Z_{ji} is called the mutual impedance between antenna i and antenna j . In the case of linear radiators, Carter's method, or the induced-emf method based upon sinusoidal current distribution, is the simplest one to use in determining the various Z 's. The method applies only to antennas shorter than a half wavelength. The self-impedance determined by this method is the same as that given by Eq. 4-1. The formulas for the mutual impedance of two parallel antennas of equal size are found in Carter's original paper or in Kraus's book.²⁸ Figure 4-28 shows the mutual impedance of two parallel half-wave antennas placed side by side. Figure 4-29 shows the mutual impedance of two parallel collinear half-wave antennas. Mutual impedances of two parallel antennas of unequal sizes have been investigated by several authors.²⁹⁻³¹ The induced-emf method has also been applied to crossed or skewed antennas^{32,33} to evaluate their mutual impedance. Refined calculations based upon Hallén's integral-equation technique are found in the works of Tai,³⁴ Bouwkamp,³⁵ and Uda and Mushiake.¹³ The last two authors also evaluated the self-impedance and mutual impedance of parallel antennas of unequal sizes, which ultimately applies to the design of Yagi-Uda arrays.

FIGURE 4-28 Mutual impedance between two parallel half-wave antennas placed side by side

FIGURE 4-29 Mutual impedance between two collinear half-wave antennas

For dipoles separated by a distance that is large compared with a wavelength, the mutual impedance between the two dipoles can be calculated by using the asymptotic formula

$$Z_{12} = \frac{jkZ_0 e^{-jkR}}{4\pi R} (\mathbf{h}_1 \cdot \mathbf{h}_2) \quad (4-25)$$

where

$$k = 2\pi/\lambda$$

$$Z_0 = (\mu_0/\epsilon_0)^{1/2}$$

R = distance between centers of dipoles

$\mathbf{h}_1, \mathbf{h}_2$ = effective height of dipoles

The formula is quite accurate for half-wave dipoles with a separation barely greater than one wavelength.

4.8 MONOPOLE ANTENNAS

Relationship to Balanced Antennas

When a monopole is mounted on an ideally infinite ground plane, its impedance and radiation characteristics can be deduced from that of a dipole of twice its length in free space. For a base-driven monopole, its input impedance is equal to one-half that of the center-driven dipole, and the radiation pattern above the infinite ground plane is identical with the upper half of the radiation pattern of the corresponding dipole. When the ground plane is of finite size, the image theorem does not apply.

Several methods have been devised to investigate the characteristics of a monopole mounted on a finite-size ground plane. The first method is due to Bolljahn,³⁶ who considers the problem from the point of view of symmetrical components. The decomposition

FIGURE 4-30a Monopole and finite-size ground plane and its decomposition into two modes of excitation

is shown in Figure 4-30a, in which the ground plane is assumed to be of the form of an infinitely thin conducting disk. For the symmetrical mode of excitation, the presence of the disk has no effect upon the radiation of the two elements. The problem is therefore the same as if the two elements were placed in free space. The antisymmetrical pair of current elements excites equal currents on the top and the bottom sides of the disk. This mode is responsible for the variation of the input impedance of the antenna as a function of the disk diameter. It is also responsible for the asymmetry of the resultant radiation pattern with respect to the ground plane. Bolljahn's original work was developed by assuming a short monopole on a disk. The entire analysis is found in Schelkunoff's book *Advanced Antenna Theory*.⁷ His study of the characteristics of large ground planes was later extended by Storer³⁷ to monopoles of arbitrary length.

Effect of Finite-Size Ground Plane on Impedance and Pattern

According to Storer, who used a variational method to formulate the problem, the change of the input impedance of a base-driven monopole erected upon a large circular ground plane can be written as

$$\Delta Z = Z - Z_0 = j \frac{60}{kd} e^{-jkd} \left| k \int_0^h \frac{I(z)}{I(0)} dz \right|^2 \quad (4-26)$$

where

Z_0 = impedance of monopole referred to an infinite ground plane, Ω

d = diameter of circular ground plane

$k = 2\pi/\lambda$

h = height of monopole

$I(z)$ = current-distribution function of monopole

$I(0)$ = base current or input current

The function $j(60/kd)e^{-jkd}$, which is independent of the current distribution, is plotted in Figure 4-30b. The real and the imaginary parts of the function are respectively equal to $(R - R_0) / \left| k \int_0^h \frac{I(z)}{I(0)} dz \right|^2$ and $(X - X_0) / \left| k \int_0^h \frac{I(z)}{I(0)} dz \right|^2$. For a quarter-wave monopole, if we assume $I(z) = I(0) \cos kz$, then

$$\left| k \int_0^h \frac{I(z)}{I(0)} dz \right| = 1$$

Thus, with a ground plane of a diameter greater than 10 wavelengths, you can see from Figure 4-30b that the variation of the resistance and of the reactance of a quarter-wave monopole is less than 1 Ω .

FIGURE 4-30b Universal curve for the change of antenna impedance as a function of the diameter of the ground plane

Radiation Pattern of a Monopole on a Circular Ground Plane*

While the effect of a ground plane upon the impedance of a monopole is not very significant, the radiation pattern is affected considerably. The pattern of such a composite antenna can be obtained quite accurately using the uniform geometrical theory of diffraction (GTD).^{38,39} For a short monopole of length h positioned at the center of a circular disk of radius a , as shown in Figure 4-31, the current on the monopole is assumed to be

$$I(z) = I_0 \frac{\sin k(h-z)}{\sin kh} \quad (4-27)$$

* The material contained in this subsection is condensed from a communication from Dr. Robert G. Kouyoumjian exclusively prepared for this handbook. The help of Dr. Kouyoumjian is gratefully acknowledged.

FIGURE 4-31 A monopole on a circular disk

If the point of observation is not near the vertical axis (θ is not close to 0 or π), the radiation field can then be expressed in the form

$$\mathbf{E} = (E_0 + E_{d1} + E_{d2}) \hat{\theta} \quad (4-28)$$

where E_0 is the geometrical optics field given by

$$E_0 = \begin{cases} \frac{jZ_0 I_0 e^{-jkR}}{2\pi R \sin kh} \left[\frac{\cos(kh \cos \theta) - \cos kh}{\sin \theta} \right], & 0 \leq \theta < \frac{\pi}{2} \\ 0, & \frac{\pi}{2} < \theta \leq \pi \end{cases} \quad (4-29)$$

and E_{d1} and E_{d2} represent, respectively, the singly and doubly diffracted field. They are given by

$$E_{d1} = -\frac{E_0 \left(a, \frac{\pi}{2}\right) a}{2\sqrt{2\pi ka \sin \theta}} \left\{ F \left[2ka \cos^2 \left(\frac{\pi}{4} + \frac{\theta}{2} \right) \right] \sec \left(\frac{\pi}{4} + \frac{\theta}{2} \right) e^{j[ka \sin \theta - (\pi/4)]} \mp \sec \left(\frac{\pi}{4} - \frac{\theta}{2} \right) e^{-j[ka \sin \theta - (\pi/4)]} \right\} \frac{e^{-jkR}}{R} \quad (4-30)$$

$$E_{d2} = -\frac{E_0 \left(a, \frac{\pi}{2}\right) a}{2\sqrt{2\pi ka \sin \theta}} \frac{e^{-j(2ka - \pi/4)}}{2\sqrt{\pi ka}} \cdot \left\{ F \left[2ka \cos^2 \left(\frac{\pi}{4} + \frac{\theta}{2} \right) \right] \sec \left(\frac{\pi}{4} + \frac{\theta}{2} \right) e^{j[ka \sin \theta - (\pi/4)]} \mp \sec \left(\frac{\pi}{4} - \frac{\theta}{2} \right) e^{-j[ka \sin \theta - (\pi/4)]} \right\} \frac{e^{-jkR}}{R} \quad (4-31)$$

where

$$F(x) = 2j\sqrt{x} e^{jx} \int_{\sqrt{x}}^{\infty} e^{-jt^2} dt \quad (4-32)$$

$$E_0 \left(a, \frac{\pi}{2}\right) = \frac{jZ_0 I_0 e^{-jka}}{2\pi a \sin kh} (1 - \cos kg) \quad (4-33)$$

In Eqs. 4-30 and 4-31, the upper sign associated with the secant functions is for $0 \leq \theta < \pi/2$, and the lower sign is for $\pi/2 < \theta \leq \pi$. Although the uniform GTD is a high-frequency method, which implies that $ka \gg 1$, in practice the result is valid even for ka as small as 2π . When the argument of the transition function $F(x)$ is greater than 10 or so, $F(x)$ is approximately equal to 1; then the sum of E_{d1} and E_{d2} yields

$$E_{d1} + E_{d2} = -E_0(a, \pi/2) \frac{a}{4} \sqrt{\frac{2}{\pi ka \sin \theta}} \left\{ \sec \left(\frac{\pi}{4} + \frac{\theta}{2} \right) e^{j[ka \sin \theta - (\pi/4)]} \right. \\ \left. \mp \sec \left(\frac{\pi}{4} - \frac{\theta}{2} \right) e^{-j[ka \sin \theta - (\pi/4)]} \left[1 + \frac{e^{-j[2ka - (\pi/4)]}}{2\sqrt{\pi ka}} \right] \right\} \frac{e^{-jkR}}{R} \quad (4-34)$$

In the axial region (θ close to 0 or π), the pattern can be found by means of an equivalent edge current.^{39,40} The total diffracted field in this case is given by

$$E_{d1} + E_{d2} = \mp jE_0 \left(a, \frac{\pi}{2} \right) \frac{a}{2} \sec \frac{\pi}{4} J_1(ka \sin \theta) \left[1 + \frac{e^{-j(2ka - \pi/4)}}{2\sqrt{\pi ka}} \right] \quad (4-35)$$

This approximately equals E_{d1} and E_{d2} given by Eqs. 4-30 and 4-31 at $ka \sin \theta \approx 5$ for $\theta \ll \pi/2$. Thus, the pattern calculated from Eq. 4-35 joins smoothly with that calculated by Eqs. 4-31 and 4-32 when $ka > 5$.

Figure 4-32 shows a typical pattern based on Eq. 4-28, the solid line, and Eq. 4-35, the dashed line. For practical purposes the term E_{d2} due to the doubly defracted rays is much smaller compared with E_{d1} except in the region where θ is close to $\pi/2$. By using a hybrid moment method jointly with GTD, it is possible to determine the input impedance of a monopole centered on a perfectly conducting circular disk.⁴¹

Monopole Mounted on the Edge of a Sheet

When a monopole is driven against an infinitely large conducting half sheet, the problem can be formulated conveniently with the aid of the dyadic Green's function pertaining to the half sheet.⁴² By transforming the resultant series into definite integrals, Sawaya, Ishizone, and Mushiaki⁴³ have been able to calculate the impedance of a monopole mounted on a half sheet in several orientations. Their results are shown in Figures 4-33 and 4-34.

These theoretical data can be used to estimate the impedance of monopoles mounted on large but finite conducting sheets. These authors also calculated the impedance of a notch antenna cut on a half sheet. The radiation patterns of short dipoles and small loops mounted on a half sheet are found in C. T. Tai's *Dyadic Green's Functions in Electromagnetic Theory*.⁴² Other work also has been reported by Pozar and Newman⁴⁴ and by Marin and Catedra⁴⁵ for the impedance and radiation patterns of monopoles located near the edges of finite half sheets or disks.

Monopole Mounted on a Conducting Box

Investigations by Bhattacharya et al.⁴⁶ and Chu et al.⁴⁷ have reported the impedance and radiation patterns of a monopole mounted at arbitrary locations on a conducting box that is comparable in size to a wavelength. Figure 4-35 shows the behavior of the admittance of a monopole as a function of frequency as the position of the monopole is moved from the center of the box face to one corner.⁴⁶

5.1 INTRODUCTION

The single-turn loop antenna is a metallic conductor bent into the shape of a closed curve, such as a circle or a square, with a gap in the conductor to form the terminals. A multiturn loop or coil is a series connection of overlaying turns. The loop is one of the primary antenna structures; its use as a receiving antenna dates back to the early experiments of Hertz on the propagation of electromagnetic waves.¹

The discussion of loop antennas is conveniently divided according to electrical size. Electrically small loops, those whose total conductor length is small compared with the wavelength in free space, are the most frequently encountered in practice. For example, they are commonly used as receiving antennas with portable radios, as directional antennas for radio-wave navigation, and as probes with field-strength meters. Electrically larger loops, particularly those near resonant size (circumference of loop/wavelength ≈ 1), are used mainly as elements in directional arrays.

The following symbols are used throughout the chapter:

λ = wavelength in free space at the frequency $f = \omega/2\pi$, when the complex harmonic time-dependence $\exp(j\omega t)$ is assumed

$\beta = 2\pi/\lambda$ = propagation constant in free space

$\zeta = \sqrt{\mu_0/\epsilon_0}$ = wave impedance of free space ($\approx 377 \Omega$)

b = mean radius of a circular loop or mean side length of a square loop

a = radius of loop conductor (All results presented are for thin-wire loops, $a/b \ll 1$.)

A = area of loop

N = number of turns

ℓ_c = length of solenoidal coil

5.2 ELECTRICALLY SMALL LOOPS

The axial current distribution in an electrically small loop is assumed to be uniform; that is, the current has the same value I_0 at any point along the conductor. For single-turn loops and multiturn loops that are single-layer solenoidal coils, measurements suggest that this is a good assumption provided the total length of the conductor ($N \times$ circumference) is small compared with the wavelength in free space, typically $\leq 0.1\lambda$, and the length-to-diameter ratio for the solenoidal coil is greater than about 3 ($\ell_c/2b \geq 3.0$).² With a uniform current assumed, the electrically small loop antenna is simply analyzed as a radiating inductor.³

Transmitting Loop

The electromagnetic field of an electrically small loop antenna is the same as that of a magnetic dipole with moment $m = I_0 NA$:

$$E_\phi = \frac{\zeta \beta^2 m}{4\pi r} \left(1 - \frac{j}{\beta r}\right) e^{-j\beta r} \sin \theta \quad (5-1)$$

$$B_\theta = \frac{-\mu_0 \beta^2 m}{4\pi r} \left(1 - \frac{j}{\beta r} - \frac{1}{\beta^2 r^2}\right) e^{-j\beta r} \sin \theta \quad (5-2)$$

$$B_r = \frac{\mu_0 \beta^2 m}{2\pi r} \left(\frac{j}{\beta r} + \frac{1}{\beta^2 r^2}\right) e^{-j\beta r} \cos \theta \quad (5-3)$$

FIGURE 5-1 Loop antenna and accompanying spherical coordinate system

FIGURE 5-2 Far-zone vertical-plane field pattern of an electrically small loop

in which the plane of the loop is normal to the polar axis of the spherical coordinate system (r, θ, ϕ) centered at the loop, as shown in Figure 5-1. In the far zone of the loop ($\lim \beta r \rightarrow \infty$), only the leading terms in Eqs. 5-1 and 5-2 are significant, and the field pattern for both E_ϕ and B_θ in the vertical plane is the simple figure eight shown in Figure 5-2.

The driving-point voltage and current are related through the input impedance of the loop, $V = ZI_0$. For electrically small loops, the impedance is the series combination of the reactance of the external inductance L^e with the radiation resistance R^r and the internal impedance of the conductor $Z^i = R^i + j\omega L^i$:

$$Z = R + j\omega L = R^r + Z^i + j\omega L^e = R^r + R^i + j\omega(L^e + L^i) \quad (5-4)$$

The internal resistance R^i accounts for ohmic loss. In the equivalent circuit for the small loop, a lumped capacitance C is sometimes placed in parallel with Z to account for the distributed capacitance between the sides of a single turn and between the turns of a solenoid, as shown in Figure 5-3. Note that a loop with a truly uniform current distribution would have no capacitance, since from the equation of continuity there would be no charge along the conductor of the loop.

The radiation resistance of the small loop is proportional to the square of the product of the area and the number of turns:

$$R^r = \frac{\zeta}{6\pi} \beta^4 (NA)^2 \quad (5-5)$$

For single-turn loops and solenoidal coils whose turns are not too closely spaced, the internal impedance is approximately

$$Z^i = z^i \times \text{total length of conductor} \quad (5-6)$$

FIGURE 5-3 Equivalent circuit for input impedance Z of an electrically small loop

in which z^i is the internal impedance per unit length of a straight conductor with the same cross section as the loop conductor.⁴ If the turns of the coil are closely spaced, the proximity effect must also be included in determining Z^i .⁵

The external inductance is determined from one of the many formulas available for the inductance of coils:⁶ For a single-turn circular loop

$$L^e = \mu_0 b [\ln(8b/a) - 2] \quad (5-7)$$

and for a single-turn square loop

$$L^e = \frac{2\mu_0 b}{\pi} [\ln(b/a) - 0.774] \quad (5-8)$$

The external inductance of a tightly wound single-layer solenoidal coil of N turns, length ℓ_c , and radius b is often approximated by Lorenz's formula for the inductance of a circumferentially directed current sheet.⁶ Numerical results from this formula can be put in a form convenient for application:

$$L^e = K \mu_0 N^2 A / \ell_c \quad (5-9)$$

in which the factor K , known as Nagaoka's constant, is shown as a function of the ratio $\ell_c/2b$ (length of the coil to the diameter) in Figure 5-4. Note that, for a long coil ($\ell_c/2b \gg 1$), $K \approx 1$. The use of Eq. 5-9 assumes that the turns of the coil are so closely spaced that the winding pitch and insulation on the conductors can be ignored; if highly accurate calculations of L^e are necessary, corrections for these factors are available in the literature.⁶

FIGURE 5-4 Nagaoka's constant K for a solenoidal coil as a function of the coil length to the diameter, $\ell_c/2b$

FIGURE 5-5 Plane-wave field incident on receiving loop

The radiation efficiency of the electrically small transmitting loop antenna is

$$\eta = \frac{\text{Time-Average Power Radiated}}{\text{Time-Average Power Supplied}} = \frac{R^r}{R^r + R^i} \quad (5-10)$$

The ohmic resistance R^i is often comparable to or larger than the radiation resistance R^r , so the radiation efficiency can be low.⁵ It can be increased by decreasing the ohmic resistance of the loop, i.e., by using a conductor of lower resistivity or larger radius.

Receiving Loop

When the electrically small loop is used as a receiving antenna, the voltage developed at its open-circuited terminals V_{OC} is proportional to the component of the incident magnetic flux density normal to the plane of the loop B_z^i :

$$V_{OC} = j\omega NAB_z^i \quad (5-11)$$

in which the incident field is assumed to be uniform over the area of the loop. This simple relation between V_{OC} and B_z^i makes the small loop useful as a probe for measuring the magnetic flux density. If a relation between the incident electric and magnetic fields at the center of the loop is known, V_{OC} can be expressed in terms of the magnitude of the incident electric field E^i and an effective height h_e . This is the case for an incident linearly polarized plane wave with the wave vector \mathbf{k}_i and the orientation shown in Figure 5-5:

$$V_{OC} = j\omega NAB^i \cos \psi_i \sin \theta_i = h_e(\psi_i, \theta_i)E^i \quad (5-12)$$

in which

$$h_e(\psi_i, \theta_i) \equiv V_{OC}/E^i = j\beta NA \cos \psi_i \sin \theta_i \quad (5-13)$$

The voltage across an arbitrary load impedance Z_L connected to the terminals of the loop with input impedance Z is determined from the Thévenin equivalent circuit in Figure 5-6:

$$V_L = V_O Z_L/(Z + Z_L) \quad (5-14)$$

FIGURE 5-6 Thévenin equivalent circuit for the receiving loop

Ferrite-Loaded Receiving Loop

The open-circuit voltage at the terminals of the electrically small receiving loop can be increased by filling the loop with a core of permeable material, usually a ferrite. The effect of the core is to increase the magnetic flux through the area of the loop, as illustrated in Figure 5-7 for a solenoidal coil with a cylindrical core placed in a uniform axial magnetic field.

The ferrite material is characterized by a complex relative initial permeability $\mu_r = \mu/\mu_0 = \mu'_r - j\mu''_r$ and a relative permittivity $\epsilon_r = \epsilon/\epsilon_0$.^{*} The material is usually selected to have a loss tangent $p_m = \mu''_r/\mu'_r$ that is small at the frequency of operation. Consequently, μ''_r is ignored in the analysis except when the power dissipated in the core is being calculated. The dimensions of the core are also assumed to be small compared with the wavelength in the ferrite $\lambda_m \approx \lambda/\sqrt{\epsilon_r \mu'_r}$ to prevent internal resonances within the core.⁷

The open-circuit voltage for a single-turn loop at the middle of a ferrite cylinder of length ℓ_r and radius b is increased by the factor μ_{rod} over the value for the same loop in free space:

$$V_{\text{OC}} = j\omega\mu_{\text{rod}}AB_z^i \quad (5-15)$$

Here the radius of the loop conductor a is ignored, and the mean radius of the loop and the core are assumed to be the same value b . The graph in Figure 5-8 shows the apparent permeability μ_{rod} as a function of the length-to-diameter ratio for the rod $\ell_r/2b$ with the relative initial permeability of the ferrite μ'_r as a parameter.⁸ Similar graphs for the apparent permeability of solid and hollow spheroidal cores are in the literature.⁹

For a single-layer solenoidal coil of length ℓ_c centered on the rod, an averaging factor F_V must be included in the open-circuit voltage to account for the decrease in the flux along the length of the coil from the maximum at the middle:

$$V_{\text{OC}} = j\omega\mu_{\text{rod}}F_VNAB_z^i \quad (5-16)$$

The empirical factor F_V , determined from an average of experimental results, is shown in Figure 5-9 as a function of the ratio ℓ_c/ℓ_r (length of the coil to length of the rod).^{10,11} For a long rod of moderate permeability ($\ell_r/2b \gg 1$, $\mu_{\text{rod}} \approx \mu'_r$) covered by a coil of equal length ($\ell_c/\ell_r = 1$), the open-circuit voltage is increased by approximately the factor 0.8 μ'_r over the open-circuit voltage for the same coil without the core.

The equivalent circuit for the impedance of the ferrite-loaded solenoidal coil is that shown in Figure 5-3 with an additional series resistor R^m included to account for the power dissipated in the core. The elements in the circuit are the radiation resistance:

$$R^r = \frac{\zeta}{6\pi} \beta^4 (\mu_{\text{rod}} F_V N A)^2 \quad (5-17)$$

^{*}The initial permeability is the derivative dB/dH in the limit as H is reduced to zero. Dielectric loss in the ferrite is ignored here, and the permittivity is assumed to be real.

FIGURE 5-7 Effect of a cylindrical ferrite core on the magnetic flux through a solenoidal coil

the resistance due to core loss:

$$R^m = \omega(\mu_{\text{rod}}/\mu_r')^2 \mu_r'' \mu_0 F_R N^2 A / \ell_c \quad (5-18)$$

and the external inductance of the loaded solenoidal coil:

$$L^e = \mu_{\text{rod}} F_L \mu_0 N^2 A / \ell_c \quad (5-19)$$

FIGURE 5-8 The apparent permeability μ_{rod} at the middle of a cylindrical rod as a function of the length-to-diameter ratio $\ell_r/2b$ with the initial permeability μ_r' as a parameter

FIGURE 5-9 The factors F_V , F_L , and F_R as functions of the ratio l_c/l_r (length of the coil to length of the rod). These factors were determined from averages of experimental data.

The internal impedance of the conductor Z_i is assumed to be the same as that for the unloaded loop. The empirical factors F_R and F_L in Eqs. 5-18 and 5-19, like F_V , were determined from an average of experimental results and are also shown as a function of the ratio l_c/l_r in Figure 5-9.^{10,11} It should be emphasized that the graphs for the three factors F_V , F_R , and F_L represent typical measured values and show only the dependence on the ratio l_c/l_r ; some dependence on the other parameters describing the coil and the rod is to be expected.

Equations 5-16 through 5-19 provide a complete description of the electrically small ferrite-loaded receiving loop (single-layer solenoidal coil with a cylindrical core). Other parameters of interest, such as the Q of the antenna, can be determined from these results. The permeability of a specific ferrite can be obtained from the manufacturer or from the extensive tables and charts in *Soft Ferrites: Properties and Applications* by E. C. Snelling.¹¹ The many parameters that are to be chosen for the ferrite-loaded loop, such as μ_r , l_r , l_c , N , etc., offer a great deal of flexibility in its design. Several discussions in the literature determine these parameters to optimize the performance for a particular application.¹²

The electromagnetic field of the ferrite-loaded transmitting loop is given by Eqs. 5-1 to 5-3 with the moment $m = \mu_{\text{rod}} F_V I_0 N A$. The ferrite-loaded loop, however, is seldom used as a transmitting antenna because of the problems associated with the nonlinearity and the dissipation in the ferrite at high magnetic field strengths.¹³

Matching Networks

A matching network is generally used to improve the power transfer to and from the electrically small loop antenna. At the frequency ω_0 , the impedance of the loop can be transformed to the resistance R_0 by using various networks, two of which are shown in Figure 5-10.¹⁴ In both arrangements, the capacitor C_1 is used to bring the loop close to resonance at ω_0 . Then the additional elements (the capacitor C_2 in Figure 5-10a, or the spacing s_2 and length of the lines l_2 in Figure 5-10b) are adjusted to make the impedance R_0 . The matches obtained with these simple networks generally have very narrow bandwidth.

FIGURE 5-10 Examples of matching networks used with electrically small loop antennas. Matching to the resistance R_0 with (a) two capacitors and with (b) shunt feed and one capacitor.

The capacitors for the circuit in Figure 5-10a are

$$C_1 = \frac{1}{\omega_0 (\omega_0 L - R \sqrt{R_0/R - 1})} \approx \frac{1}{\omega_0 (\omega_0 L - \sqrt{RR_0})} \quad (5-20)$$

$$C_2 = \frac{1}{\omega_0 R_0} \sqrt{R_0/R - 1} \approx \frac{1}{\omega_0 \sqrt{RR_0}} \quad (5-21)$$

in which the approximations on the right apply for the practical case $R_0/R \gg 1$. Figure 5-10b is for a symmetrical shunt-driven loop. Sometimes an asymmetrical configuration is used, in which the length of one of the two lines is set to zero.

5.3 ELECTRICALLY LARGE LOOPS

As the electrical size of the loop antenna is increased, the current distribution in the loop departs from the simple uniform distribution of the electrically small loop. For single-turn loops, this departure has a significant effect on performance when the circumference is greater than about 0.1λ . For example, the radiation resistance of an electrically small circular loop with a uniform current, as predicted by Eq. 5-5, is about 86 percent of the actual resistance when $\beta b = 2\pi b/\lambda = 0.1$ and only about 26 percent of the actual resistance when $\beta b = 0.3$.

Of the possible shapes for an electrically large loop antenna, the single-turn thin-wire circular loop has received the most attention, both theoretical and experimental. The popularity of the circular loop is due in part to its straightforward analysis by expansion of the current in the loop as a Fourier series:

$$I(\phi) = I_0 + 2 \sum_{n=1}^m I_n \cos n\phi \quad (5-22)$$

in which the angle ϕ is defined in Figure 5-1.¹⁵ Measurements on electrically large loops with other shapes, such as the square loop, show that their electrical performance is qualitatively similar to that of the circular loop; therefore, only the circular loop will be discussed here.¹⁶

FIGURE 5-11 Methods of driving the circular-loop antenna: (a) Full-loop antenna driven from parallel-wire transmission line; (b) Half-loop antenna driven from coaxial transmission line

Circular-Loop Antenna

The theoretical model for the circular-loop antenna generally assumes a point-source generator of voltage V at the position $\phi = 0$, making the input impedance of the loop $Z = R + jX = VI/I(\phi = 0)$. In practical applications, the full-loop antenna is usually driven from a balanced source, such as a parallel-wire transmission line, and the half-loop antenna, the analog of the electric monopole, is driven from a coaxial line, as in Figure 5-11. The point-source generator of the theoretical model contains no details of the geometry of the feed point, and it is not strictly equivalent to either of these methods of excitation. However, theoretical current distributions, input impedances, and field patterns computed with the point-source generator and 20 terms in the Fourier series (Eq. 5-22) are generally in good agreement with measured values.* Thus, the theory serves as a useful design tool.

For the half-loop antenna (Figure 5-11b), an accurate analysis, based on the Fourier series, is available that includes the details of the feeding coaxial line.¹⁷ Results from this analysis are in excellent agreement with measurements and show such things as the change in the input impedance of the half-loop antenna with a change in the characteristic impedance of the feeding coaxial line.

In Figures 5-12 and 5-13, the input impedance of a loop constructed from a perfect conductor is shown as a function of the electrical size of the loop $\beta b = 2\pi b/\lambda$ (circumference/wavelength) for various values of the radius of the conductor, indicated by the *thickness parameter* $\Omega = 2 \ln(2\pi b/a)$. These impedances are for full-loop antennas; for half-loop antennas with the same radius and conductor size, impedances are approximately one-half of these values. The reactance X is seen to be zero at points near $\beta b = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$ (antiresonant points) and $\beta b = 1, 2, 3, \dots$ (resonant points). The resistance obtains relative maxima near the points of antiresonance and relative minima near the points of resonance. Impedances computed from Eqs. 5-5 and 5-7, which apply to electrically small loops, are also shown in Figures 5-12 and 5-13; the inaccuracy of these formulas with increasing βb is evident.

When the electrical size of the loop is near that for resonance ($\beta b = 1, 2, 3, \dots$), the dominant term in the Fourier series for the current (Eq. 5-22) is the one with $n = \text{integer } (\beta b)$. For example, near the first resonance $\beta b \approx 1$, the current in the loop is approximately $I(\phi) = 2I_1 \cos \phi$, and the loop is commonly referred to as a resonant loop. The resonant loop ($\beta b \approx 1$) is the most frequently used electrically large loop. It has a reasonable input resistance, $R \approx 100 \Omega$, for matching to a transmission line, particularly when compared with the resistance of the antiresonant loop ($\beta b \approx 0.5$), which may be larger than $10 \text{ k}\Omega$.

*The theoretical results in Figures 5-12, 5-13, 5-15 to 5-19, and 5-21 were computed by the author by using 20 terms in this series.

FIGURE 5-12 Input resistance of circular-loop antenna versus electrical size (circumference/wavelength)

FIGURE 5-13 Input reactance of circular-loop antenna versus electrical size (circumference/wavelength)

FIGURE 5-14 Schematic of current distribution in (a) resonant loop and in (b) the approximately equivalent pair of dipoles

Resonant Circular Loop

The current in the resonant loop has maxima at the generator, $\phi = 0$, and at the diametrically opposite point, $\phi = \pi$, with nodes at $\phi = \pi/2$ and $3\pi/2$. On examination of Figure 5-14, the current is seen to be roughly equivalent to that in a pair of parallel dipole antennas driven in phase and with a spacing approximately equal to the diameter of the loop.

The far-zone field patterns for the resonant loop shown in Figure 5-15a–c are also similar to those for the pair of dipoles; they have little resemblance to the figure-eight pattern of the electrically small loop, Figure 5-2. There are two components to the electric field, E_θ and E_ϕ . E_θ is zero in the horizontal plane $\theta = \pi/2$ and in the vertical plane $\phi = 0, \pi$, while E_ϕ is small in the vertical plane $\phi = \pi/2, 3\pi/2$. The amplitude patterns are symmetrical about

FIGURE 5-15 Far-zone electric field for loop with $\beta b = 1.0$, $\Omega = 10$: (a) Horizontal-plane field pattern $|E_\phi|$, $\theta = \pi/2$; (b) Vertical-plane field pattern $|E_\theta|$, $\phi = \pi/2, 3\pi/2$; (c) Vertical-plane field pattern $|E_\phi|$, $\phi = 0, \pi$

FIGURE 5-16 Far-zone electric field patterns in upper hemisphere: (a) Electrically small loop, $\beta b = 1$; (b) Resonant loop, $\beta b = 1.0$

the plane $\theta = \pi/2$ and $\phi = 0, \pi$ owing to the geometrical symmetry of the loop, and they are nearly symmetrical about the plane $\phi = \pi/2, 3\pi/2$, because of the dominance of the term $2I_1 \cos \phi$ in the current distribution. At the maxima ($\theta = 0, \pi$) of the bidirectional pattern, the electric field is linearly polarized in the direction \hat{y} .

To help with the visualization of the electric field, three-dimensional amplitude patterns for the electrically small loop and the resonant loop are presented in Figure 5-16. Each drawing is a series of patterns on planes of constant angle ϕ ; only the patterns in the upper hemisphere ($0 \leq \theta \leq \pi/2$) are shown, since those in the lower hemisphere are identical.

The directivity of the circular loop in the direction $\theta = 0$ or π is shown as a function of the electrical size βb in Figure 5-17; it is about 3.4 dB for $\beta b = 1.0$ and has a maximum of about 4.5 dB for $\beta b = 1.4$. The directivity is fairly independent of the parameter Ω for $\beta b \leq 1.4$.

FIGURE 5-17 Directivity of circular-loop antenna for $\theta = 0, \pi$ versus electrical size (circumference/wavelength)

The resonant loop antenna is attractive for practical applications because of its moderate input resistance and symmetrical field pattern with reasonable directivity. The bidirectional nature of its pattern, however, is usually not desired, and a reflector or an array of loops is used to make the pattern unidirectional.

For most antenna problems, the far-zone field described previously is of interest; however, for some applications the field close to the loop may be required. Expressions for the near field of the circular-loop antenna with uniform current or the Fourier series representation in Eq. 5-22 have been obtained using various methods.¹⁸

Circular Loop with Planar Reflector

The pattern of the resonant loop is made unidirectional and the directivity in the direction $\theta = 0$ is increased by placing the loop over a planar reflector. The theoretical results for an infinite perfectly conducting reflector (Figure 5-18) show that the directivity is greater than 9 dB for spacings between the loop and the reflector in the range $0.05 \leq d/\lambda \leq 0.2$.¹⁹ Over this same range of spacings, the input impedance $Z = R + jX$ (Figure 5-19) has values that are easily matched: the resistance is reasonable ($R \leq 135 \Omega$), and the reactance is small ($|X| \leq 20 \Omega$).

The theoretical results for an infinite reflector are in good agreement with measured data for finite square reflectors of side length s . The directivities measured by Adachi and Mushiake²⁰ (Figure 5-18) for a reflector with $s/\lambda = 1.2$ and $d/\lambda \leq 0.26$ are slightly higher than those for an infinite plane, while the input impedances measured by Rojarayanont and Sekiguchi²¹ (Figure 5-19) show variations with reflector size, $0.48 \leq s/\lambda \leq 0.95$, but general agreement with the results for an infinite plane.

Electric field patterns measured by Rojarayanont and Sekiguchi²¹ for resonant loops one-quarter wavelength, $d/\lambda = 0.25$, in front of square reflectors are shown in Figure 5-20. The shaded area in each figure shows the variation in the pattern that is a result of changing the size of the square reflector from $s/\lambda = 0.64$ to $s/\lambda = 0.95$.

FIGURE 5-18 Directivity of circular-loop antenna, $\beta b = 1.0$, for $\theta = 0$ versus distance from reflector d/λ . Theoretical curve is for infinite planar reflector; measured points are for square reflector.

FIGURE 5-19 Input impedance of circular-loop antenna, $\beta b = 1.0$, versus distance from reflector d/λ . Theoretical curves are for infinite planar reflector; measured points are for square reflector.

Coaxial Arrays of Circular Loops

Loop antennas, like linear antennas, can be combined in an array to improve performance. The most common array of circular loops is the coaxial array in which all the loops are parallel and have their centers on a common axis; an example of a coaxial array

FIGURE 5-20 Measured far-zone electric field patterns for loop with $\beta b = 1.0$ over square reflector, $d/\lambda = 0.25$. Inner curve $s/\lambda = 0.95$; outer curve $s/\lambda = 0.64$. (a) Vertical-plane field pattern $|E_\theta|$, $\phi = \pi/2, 3\pi/2$. (b) Vertical-plane field pattern $|E_\phi|$, $\phi = 0, \pi$. (Measured data from Rojarayanont and Sekiguchi)

is shown later in the inset of Figure 5-22. The Fourier-series analysis for the single loop is easily extended to the coaxial array when all the driven loops are fed at a common angle, e.g., $\phi = 0$ in Figure 5-1. The current distribution in each loop is expressed as a series of trigonometric terms like that in Eq. 5-22. The simplicity of the analysis results from the orthogonality of the trigonometric terms, which makes the coupling between loops occur only for terms of the same order n . Thus, if all the driven loops in the array are near resonant size, $\beta b \approx 1$, the term $n = 1$ is the dominant one in the current distributions for all loops; i.e., the current is approximately proportional to $\cos \phi$ in all loops.

When all the elements in the loop array are driven, the same procedures that are used with arrays of linear elements can be applied to select the driving-point voltages to optimize certain parameters, such as directivity.²² The feed arrangement needed to obtain the prescribed driving-point voltages, however, is very complex for more than a few elements in the array. As a result, a simpler and more economical arrangement, an array containing only one driven element and several parasitic loops, is often used (a *parasitic loop* is a continuous wire with no terminals).

When a single, closely spaced parasite is used with a driven loop, the parasite may act as a director or as a reflector. This is illustrated in Figure 5-21, in which electric field patterns are shown for a driven loop ($\beta b_2 = 1.0$) and a parasitic loop with the spacing $d/\lambda = 0.1$. For loops of the same electrical size ($\beta b_1 = \beta b_2 = 1.0$), the maxima in the pattern at $\theta = 0, \pi$ are nearly equal. The parasitic loop that is slightly smaller than the driven loop ($\beta b_1 = 0.95$) acts as a director, producing a maximum in the pattern at $\theta = \pi$, while the parasitic loop that is slightly larger than the driven loop ($\beta b_1 = 1.05$) acts as a reflector, producing a maximum in the pattern at $\theta = 0$. This behavior is very similar to that observed for a resonant linear antenna with a closely spaced parasite.

The driven loop of electrical size $\beta b_2 = 1.2$ ($\Omega_2 = 11$, $a_1 = a_2$) with a single parasite was studied in detail by Ito et al.²³ In that study, the optimum director was determined to be a loop with $\beta b_1 \approx 0.95$ and spacing $d/\lambda \approx 0.10$. This produced a directivity of about 7 dB at $\theta = \pi$. The optimum reflector was a loop with $\beta b_1 \approx 1.08$ and a spacing $d/\lambda \approx 0.15$. This produced a directivity of about 8 dB at $\theta = 0$. Note that, for this case, the optimum director and the optimum reflector are both smaller than the driven loop.

A Yagi-Uda array of loops with a single reflector (element 1), an exciter (the driven element 2), and several directors of equal size βb and equal spacing d/λ is shown in the

FIGURE 5-21 Far-zone electric field patterns $|\mathbf{E}_\phi|$ in plane $\phi = 0, \pi$ for driven loop with single parasite, $\beta b_2 = 1.0$, $d/\lambda = 0.1$, $\Omega_1 = \Omega_2 = 20$

FIGURE 5-22 Directivity of Yagi-Uda array of circular-loop antennas for $\theta = 0$ versus number of directors, director spacing $d/\lambda = 0.2$

inset of Figure 5-22.* As in its counterpart with linear elements, in the Yagi-Uda array of loops the reflector-exciter combination acts as a feed for a slow wave that propagates along the array of directors.²⁴ The lowest-order propagating wave (mode) exists for directors less than about resonant size ($\beta b \leq 1.0$) with spacings less than about a half wavelength ($d/\lambda \leq 0.5$).²⁵ An array supporting this mode has an end-fire pattern with a linearly polarized electric field at the maximum, $\theta = 0$.

The procedure for designing a Yagi-Uda array of loops is the same as for an array with linear elements.²⁶ The isolated reflector-exciter combination is usually chosen to have maximum directivity in the direction $\theta = 0$. For example, the optimized two-element array described previously might be used. The number, size, and spacing of the directors are then adjusted to obtain the desired performance, such as specified end-fire directivity. The maximum end-fire directivity is determined by the electrical length of the array L/λ (L is the distance from the exciter to the last director). The larger the number of directors within the length L , the smaller the electrical size of the directors will be for maximum directivity, typically $0.8 \leq \beta b \leq 1.0$.

As an example, the directivity of a Yagi-Uda array of loops with the director spacing $d/\lambda = 0.2$ is shown as a function of the number of directors or the length of the array L/λ in Figure 5-22. Two theoretical curves and two sets of measured data are shown. All the results agree to within about 1 dB, even though they are for different reflector-exciter combinations and slightly different director sizes.[†]

*In the literature of amateur radio the Yagi-Uda array of loops, usually square loops, is referred to as a *quad antenna*.

†The parameters used by the different investigators are Appel-Hansen, $\beta b_1 = \beta b_2 = 1.10$, d_{12}/λ optimized for the isolated reflector-exciter, and βb optimized for each length L/λ ; Takata and Sekiguchi, $\beta b_1 = 1.05$, $\beta b_2 = 1.20$, $d_{12}/\lambda = 0.15$, and βb optimized for each length L/λ ; Shoamanesh and Shafai (1979), $\beta_1 b = 1.05$, $\beta_2 b = 1.10$, $d_{12}/\lambda = 0.1$, and $\beta b = 0.9$ for all lengths L/λ .

FIGURE 5-23 Coaxial array of half-loop antennas. Spacing between loops and lengths of interconnecting transmission lines can be adjusted to change field pattern of the array.

Arrays can also be formed using the half-loop antenna shown in Figure 5-11*b* as the element.²⁷ The coaxial loops can be fed individually, used as parasites, or they can be connected in series by transmission lines below the image plane and fed at a single point, as in Figure 5-23. In this arrangement, the spacing between the loops and the lengths of the transmission lines can be adjusted to change the field pattern of the array.

5.4 SHIELDED-LOOP ANTENNA

For certain applications it is desirable to position the terminals of the loop antenna precisely so as to produce geometrical symmetry for the loop and its connections about a plane perpendicular to the loop. This can often be accomplished by using the so-called shielded loop. Figure 5-24*a* is an example of a shielded receiving loop whose external surface is symmetrical about the yz plane.²⁸

With reference to Figure 5-24*a*, the thickness of the metal forming the shield is chosen to be several skin depths; this prevents any direct interaction between the currents on the internal and the external surfaces of the shield. The effective terminals of the loop antenna are at the ends of the small gap AB . The inner conductor and the shield form a coaxial transmission line of length $h + \pi b$ connecting the gap with the load impedance Z_L . Thus, the effective load impedance Z_L at the gap is Z_S transformed by the length of transmission line $h + \pi b$.

The receiving antenna in Figure 5-24*a* is easily analyzed by considering the loop, Figure 5-24*b*, and the transmission line, Figure 5-24*c*, separately. The incident field produces a current on the external surface of the shield; the current passes through the effective impedance Z_L , producing the voltage V_L , which for an electrically small loop can be determined from Eqs. 5-12 and 5-14. This voltage is transmitted over the coaxial line to become V_S at the load impedance Z_S .

Other examples of the shielded loop are shown in Figure 5-25. A balanced version of the loop in Figure 5-24*a* is in Figure 5-25*a*, and a method for feeding a loop in front of a planar reflector is in Figure 5-25*b*.

To illustrate a typical use of the shielded loop, consider the electrically small receiving loop placed in an incident linearly polarized electromagnetic plane wave with the wave

FIGURE 5-24 (a) Shielded-loop antenna (b) with equivalent antenna and (c) equivalent transmission line

vector \mathbf{k}_i , as in Figure 5-26. This is the same geometry as in Figure 5-5, except that the terminals of the loop are at the angle $\phi = \phi_L$ instead of $\phi = 0$, and $\phi_i = \pi$, $\psi_i = 0$. The loop in this example might be an antenna in a direction finder with the direction of the incident wave to be determined by placing a null of the field pattern in the direction of \mathbf{k}_i .

FIGURE 5-25 (a) Balanced shielded-loop antenna and (b) method of feeding loop antenna in front of planar reflector

FIGURE 5-26 Receiving loop in plane-wave incident field

The voltage at the open-circuited terminals of the electrically small loop, determined from the Fourier-series analysis, is approximately*

$$V_{OC} = j\omega AB^i (\sin \theta_i - 2j\beta b \cos \phi_L) \quad (5-23)$$

For many applications, the second term in Eq. 5-23 is negligible, since $\beta b \ll 1$ for an electrically small loop. In other applications, however, this term may represent a significant contribution to the response. For example, the sensitivity of the antenna in the direction finder is decreased by this term because it fills in the nulls of the $\sin \theta_i$ field pattern (for $\beta b = 0.1$, $\phi_L = 0$, the minima in the pattern are only 14 dB below the maxima).

The second term in Eq. 5-23 can be made insignificant by reducing the electrical size of the loop βb ; however, this will also decrease the sensitivity, because the area of the loop is decreased. An alternative is to make this term zero by placing the terminals of the loop precisely at $\phi_L = \pm \pi/2$ ($\cos \phi_L = 0$). This can be accomplished by using a shielded loop as in Figure 5-24a or Figure 5-25a.

5.5 PULSE-EXCITED CIRCULAR-LOOP ANTENNA

In the treatment presented so far, the performance of the loop antenna has been described for harmonic time dependence, which is the case for most practical applications. However, there are instances when the loop antenna is used with pulse excitation, such as in some proposed ultra-wideband communications systems. With pulse excitation, the time delay between pulses can be used to identify the radiation from different points on the loop, and this provides some physical insight into how the loop radiates energy. The details for the calculations are in the literature,²⁹ and only a qualitative description for the radiation will be given here.³⁰

When the circular loop is excited by a voltage pulse, such as a Gaussian, pulses of charge travel around the loop at roughly the speed of light, c : a positive pulse travels in the clockwise direction, and a negative pulse travels in the counterclockwise direction, as shown in Figure 5-27a. When these pulses have traveled once around the loop, they return to the source, where they are partially absorbed and partially transmitted, as shown in Figure 5-27b. This process is repeated until there is no more charge left on the loop.

*Eq. 5-23 is a more accurate formula than Eq. 5-12, which is also for the open-circuited voltage of the electrically small loop. It contains an additional term not in Eq. 5-12, the second term in the parentheses, which is proportional to βb . When $\beta b \ll 1$, Eq. 5-23 reduces to Eq. 5-12 with $N = 1$, and $\psi_i = 0$.

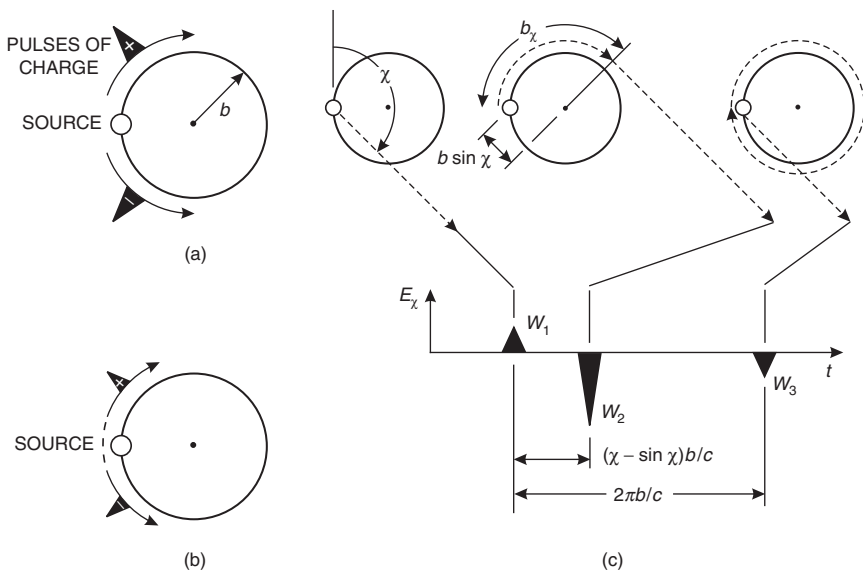

FIGURE 5-27 Schematic drawings for pulse-excited circular-loop antenna. (a) Pulses of charge leaving source and traveling around loop. (b) Pulses of charge after completing one trip around loop and passing through source. (c) Time history of far-zone electric field radiated by loop. Results are shown in the plane of the loop for the radiation due to the positive pulse of charge making one trip around the loop.

The far-zone electric field produced by one of these pulses of charge, the positive one traveling in the clockwise direction once around the loop, is described schematically in Figure 5-27c. For this example, the width of the pulse is small compared with the time for light to travel around the perimeter of the loop ($2\pi b/c$), and the time history of the field is shown for one angle of observation in the plane of the loop, $\chi = 3\pi/4 = 135^\circ$.

Three wavefronts can be distinguished in Figure 5-27c.³⁰ The wavefronts W_1 and W_3 are produced when the pulse of charge leaves the source and when it is absorbed/transmitted at the source, respectively. The wavefront W_2 is continuously produced as the pulse propagates around the loop. Wavefront W_2 appears to originate at a point on the loop where the tangent line to the loop points in the direction of the observer. As indicated in the figure, this can be ascertained from the time of arrival of W_2 relative to W_1 . The radiation from the negative pulse of charge in Figure 5-27a and from all of the subsequent pulses, Figure 5-27b, can be obtained in a similar manner.

A simple analogy can be constructed between the radiation from this loop and the radiation from a moving point charge.³⁰ The radiation arising at the source, wavefronts W_1 and W_3 , is analogous to the radiation that occurs when a point charge is accelerated in a direction parallel to its velocity (*bremsstrahlung*), and the radiation that occurs along the loop, wavefront W_2 , is analogous to the radiation that occurs when a point charge is accelerated in a direction normal to its velocity (*synchrotron radiation*).

When the loop is excited with a time-harmonic signal, a cosinusoid, each half of the cosinusoid can be considered to be a pulse. The radiation is then that due to a train of positive and negative pulses of charge—the positive pulses being separated in time by the period of the cosinusoid, $T = 2\pi/\omega = \lambda/c$. Notice that the charge on the loop from consecutive positive pulses will add when the travel time around the loop is T . This occurs for $\beta b = 2\pi b/\lambda = 1$, which is the condition for resonance stated earlier in connection with the input impedance of the loop.

In practical applications, it may be desirable to eliminate or reduce the amplitude of some of the pulses radiated by the loop. This can be accomplished by incorporating discrete or continuous resistive loading along the wire of the loop.^{30,31}

5.6 ADDITIONAL TOPICS

The brevity of this review requires omission of many interesting topics concerning loop antennas. In recent years there has been considerable study of loop antennas in close proximity to or embedded in material media such as the ocean, the earth, and biological tissue. The electrical characteristics of loops in these instances can be quite different from those of loops in unbounded free space, as described in this review. The major applications of this work are in the areas of subsurface communication and detection (geophysical prospecting) and the study of the interaction of electromagnetic radiation with biological systems.

The loop antenna near a planar interface separating two semi-infinite material regions, such as the air and the earth, has been investigated extensively. When the loop is electrically small, it can be approximated by an elementary magnetic dipole, and the electromagnetic field away from the loop can be determined from the classical analysis of Sommerfeld.³² If the field near the electrically small loop is required, the approximation by a magnetic dipole may no longer be adequate, and a loop with a finite radius and a uniform current must be considered.³³ For the electrically large loop near a planar interface, an analysis that allows a nonuniform current in the loop, such as the Fourier-series analysis for the circular loop,³⁴ must be used.

The performance of a loop embedded in a material can be altered significantly by placing the loop in a dielectric cavity, such as a sphere, to form an insulated loop. The electrical size and shape of the insulating cavity and the location of the loop in the cavity can be used to control the electromagnetic field and input impedance of the antenna.³⁵

Models have been developed to analyze a loop antenna placed near the human body, and the results have been used for two different purposes.³⁶ In one case the concern is the possible hazard due to the electromagnetic energy deposited in the body. In the other case the concern is the effect the body has on the performance (impedance and pattern) of a loop antenna contained in a personal communications device, such as a pager.

6.9 TYPICAL SMALL ANTENNAS.	6-27

6.1 THE DEFINITION OF ELECTRICALLY SMALL

The definition of an electrically small antenna can be somewhat ambiguous. Often the definition of a small antenna is one having overall dimensions (including any ground plane image) less than one-quarter wavelength ($\lambda/4$), one-eighth wavelength ($\lambda/8$), or one-tenth wavelength ($\lambda/10$). In previous editions of this *Handbook* and in his work on small antennas,¹ Wheeler defined the small antenna as one whose volume occupies a small fraction of one radiansphere. The *radiansphere* is a spherical volume having a radius of $\lambda/2\pi$.² The significance of the radiansphere dimension is that it is approximately the region surrounding the small antenna primarily occupied by the stored or reactive energy of its near electric and magnetic fields.

The electrical size or volume of the small antenna is defined by the value of ka , where k is the free-space wavenumber $2\pi/\lambda$, and a is the radius of an imaginary sphere circumscribing the maximum dimension of the antenna, as illustrated in Figure 6-1. Figure 6-1 illustrates the definition of a for both a free-space dipole-like antenna and a monopole-like antenna that requires a ground plane for operation. If the finite ground plane is sufficiently large so the monopole's impedance is similar to that exhibited by the monopole on an infinite ground plane, the dimensions of the ground plane do not need to be included in the definition of a . However, if the size and shape of the finite ground plane or the location of the monopole on the ground plane are such that the monopole's impedance is remarkably different from that exhibited by the monopole on an infinite ground plane, the dimensions of the ground plane structure generally need to be included in the definition of a .

Wheeler's statement that the small antenna is one occupying a small fraction of the radiansphere has led to the commonly accepted electrical size limit for an electrically small antenna being $ka \leq 1$. Examination of Wheeler's work^{3,4} and the work of Adler et al⁵ reveals that they describe the small antenna as having a maximum dimension less than the radian length, $\lambda/2\pi$. From the definition of a in Figure 6-1 being one-half the antenna's maximum dimension, this defines a value of $ka = 0.5$ as the electrical size limit for the electrically small antenna. You could argue that this lower value of ka simply makes the definition of an electrically small antenna more stringent. However, examining the impedance properties of a number of electrically small wire antennas, it becomes evident that many small antennas

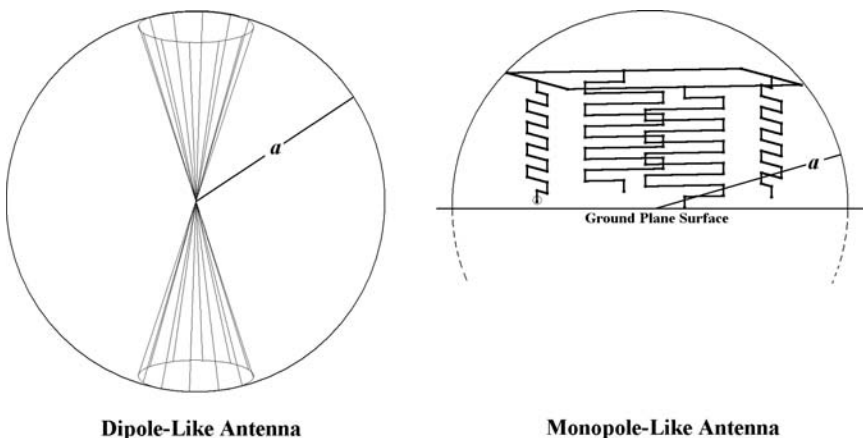

FIGURE 6-1 Definition of the radius a of an imaginary sphere circumscribing the maximum dimension of a free-space dipole-like antenna and monopole-like antenna mounted on a ground plane

exhibit similar behavior near the $ka = 0.5$ limit. As an example, the radiation resistances of certain classes of small dipole and monopole wire antennas converge to the value of the radiation resistance of the straight-wire dipole or monopole of the same height near $ka = 0.5$, independent of their total wire length or geometry.^{6,7} For these reasons, the definition of an antenna being electrically small is taken to be one where $ka \leq 0.5$.

6.2 THE ELECTRICALLY SMALL TRANSMIT ANTENNA

The feedpoint impedance of an antenna is defined as $Z_A(\omega) = R_A(\omega) + jX_A(\omega)$, where $R_A(\omega)$ is the frequency dependent feedpoint resistance, $X_A(\omega)$ is the frequency dependent feedpoint reactance, and ω is the radian frequency $2\pi f$, where f is the frequency in Hz. The frequency dependent resistance contains both radiation $[R_r(\omega)]$ and loss $[R_l(\omega)]$ terms from which the antenna's frequency dependent radiation efficiency $[\eta_r(\omega)]$ is determined using

$$\eta_r(\omega) = \frac{R_r(\omega)}{R_A(\omega)} = \frac{R_r(\omega)}{R_r(\omega) + R_l(\omega)} \quad (6-1)$$

The electrically small antenna behaves as either a lossy capacitor (C), a lossy inductor (L), or a combination of both, and its feedpoint impedance takes the form of a series or parallel RLC circuit. Because it behaves similarly to a lossy circuit element, it is often convenient to describe the properties of the small antenna in terms of circuit equivalent concepts, particularly the radiation power factor (P), quality factor (Q), fractional bandwidth (FBW), efficiency (η), and impedance matching. These will be discussed in later sections.

Consider the electrically small antenna connected to a transmitter or source through a lossless transmission line as illustrated in Figure 6-2. The source is represented by a Thevenin equivalent circuit having a voltage $V_s(\omega)$ and an impedance $Z_s(\omega)$ that are both assumed to be real and constant for all values of ω . The transmission line is assumed to have a real characteristic impedance $Z_{CH} = R_{CH}$. For simplicity in the transmission line and circuit analysis, it is also assumed that $R_{CH} = Z_s(\omega) = R_s$. The feedpoint impedance of the electrically small antenna is represented by a series RLC circuit (equivalent to a lossy capacitor) or by a parallel RLC circuit (equivalent to a lossy inductor).

The primary design objective when using the small antenna in the transmit mode is to radiate as much of the available source power as possible. The amount of power radiated by the small antenna is a function of two factors: the impedance match (or mismatch) between the antenna and the source (including the feeder transmission line), and the

FIGURE 6-2 Series and parallel RLC equivalent circuits that can be used to represent the frequency dependent feedpoint impedance of the electrically small antenna

antenna's radiation efficiency. The level of impedance mismatch between the antenna and the source is characterized by using the antenna's VSWR, which is given by

$$\text{VSWR}(\omega) = \frac{1 + |\Gamma(\omega)|}{1 - |\Gamma(\omega)|} \quad (6-2)$$

where Γ is the usual reflection coefficient given by

$$\Gamma(\omega) = \frac{Z_A(\omega) - Z_{CH}}{Z_A(\omega) + Z_{CH}} \quad (6-3)$$

If the source drives the input of the lossless transmission line with a forward power, P_{FWD} , the total power incident at the antenna's feedpoint terminal is $P_{\text{INC}} = P_{\text{FWD}}$, and the total power accepted by (delivered to) the antenna, P_A , is given by

$$P_A = (1 - |\Gamma|^2) P_{\text{INC}} \quad (6-4)$$

The total power radiated by the antenna, P_r , is a function of the antenna's radiation efficiency and is given by

$$P_r = \eta_r P_A \quad (6-5)$$

Very often it is convenient to define the antenna's overall or realized efficiency, which is defined as the ratio of radiated power to incident power. The previously defined radiation efficiency of the antenna is the ratio of radiated power to accepted power. The realized efficiency of the antenna is given by

$$\eta_0(\omega) = \frac{P_r}{P_{\text{INC}}} = \eta_r(\omega) [1 - |\Gamma(\omega)|^2] \quad (6-6)$$

Radiating most of the available source power (P_{INC}) requires the small antenna to have high radiation efficiency and a reasonable impedance match to the source and feeder transmission line. The small antenna will radiate the same total power as any other antenna having the same values of radiation efficiency and VSWR, independent of its size relative to the operating wavelength. That said, achieving high efficiency and a good impedance match with an electrically small antenna can be challenging.

Finally it is important to note that the concept of designing the small antenna to match the impedance of free-space is not valid. All small antennas, regardless of size or geometry, are inherently matched to free-space. The only design issues to consider in determining the amount of radiated power are the antenna's radiation efficiency and VSWR: the small antenna must be impedance matched to the source.

6.3 THE ELECTRICALLY SMALL DIPOLE AND LOOP ANTENNAS

Prior to introducing the equivalent circuit concepts of radiation power factor, quality factor, fractional bandwidth, and impedance matching, the basic performance properties and characteristics of the electrically small dipole and loop antennas are described.

**Dipole****Loop**

FIGURE 6-3 Depictions of the straight-wire dipole and circular loop antennas. The straight-wire dipole has an overall length l and a conductor diameter d . The circular loop has a circumference C and a conductor diameter d .

These basic antenna elements are the foundation or starting point for the design of virtually all electrically small antennas. In some manner, all electrically small antenna designs can be shown to be derivatives of the simple straight-wire dipole, monopole, or loop antennas.*

The straight-wire dipole and circular loop antennas are depicted in Figure 6-3. The straight-wire dipole has an overall length l and a conductor diameter d . The circular loop has a circumference C and a conductor diameter d . The basic performance properties of interest include the feedpoint radiation and loss resistances, the feedpoint reactance, radiation efficiency, VSWR, directivity, gain, bandwidth, and quality factor. The bandwidth and quality factor of these antennas will be discussed in the next section.

The impedance properties of a straight-wire dipole antenna, having a length $l = 1$ m and a conductor diameter $d = 5$ mm ($l/d = 200$), are depicted in rectangular and Smith Chart format in Figure 6-4 over a frequency range of 5 through 150 MHz. The properties of the dipole are simulated using the NEC4 engine of EZNEC/4 Pro.⁸ Copper conductor loss is included in these results. The straight-wire dipole exhibits its first natural resonance $[X_A(\omega_0) = 0]$ at an approximate radian frequency $\omega_0 \approx c\pi/l$, where c is the speed of light in a vacuum. This first natural resonance is a series resonance, where the frequency derivative of the feedpoint reactance at the resonant frequency $[X'(\omega_0)]$ is greater than zero. The first natural resonant frequency for the dipole is approximately 142 MHz.

Below the first natural resonant frequency, the straight-wire dipole's feedpoint reactance is always negative (capacitive) and approaches $-\infty$ as $\omega \rightarrow 0$. The radiation resistance of the dipole approaches 0 as $\omega \rightarrow 0$. At DC, the dipole is an open circuit. At frequencies

* In some instances, the electrically small antenna can be shown to be a derivative of the basic slot radiator.

FIGURE 6-4 Feedpoint impedance of the straight-wire dipole antenna having an overall length of 1 m and a conductor diameter of 5 mm

near and below the small antenna limit, the radiation resistance of the straight-wire dipole is approximately given by⁹

$$R_r^d \approx 20\pi^2 \left(\frac{l}{\lambda} \right)^2 \quad (6-7)$$

which illustrates the radiation resistance's ω^2 behavior at low frequencies. The decreasing value of radiation resistance and the increasing value of capacitive reactance result in very high values of VSWR at low frequencies. The VSWR ($Z_{CH} = 50 \Omega$) of the 1-m dipole antenna as a function of frequency is presented in Figure 6-5. At values of $ka \leq 0.5$ ($f \leq 47.7$ MHz), the VSWR approaches values in excess of several thousand, making it impractical to deliver power to the dipole using a practical transmission line.

FIGURE 6-5 VSWR of the straight-wire dipole antenna having an overall length of 1 m and a conductor diameter of 5 mm

FIGURE 6-6 Radiation efficiency of the straight-wire dipole antenna having an overall length of 1 m and a conductor diameter d . Radiation efficiency curves are presented for several values of conductor diameter.

To calculate the radiation and realized efficiency of the small dipole, its loss resistance must be determined. If the skin depth δ in the conductor is somewhat less than $d/2$, the loss resistance of the dipole can be approximated as¹⁰

$$R_l^d = \frac{l\rho}{2\pi d\delta} \approx \frac{l}{2\pi d} \sqrt{\frac{kc\mu_0\rho}{2}} \quad (6-8)$$

where ρ is the resistivity of the conductor and μ_0 is the permeability of free-space. For δ somewhat greater than $d/2$, the loss resistance of the small dipole can be approximated by $R_l^d \approx 2l\rho/(\pi d^2)$. To obtain the approximation of loss resistance in Eq. 6-8, it is assumed that the current on the dipole has a cosine dependence over the length of the conductor and that the current density decays exponentially from its value at the surface of the conductor.

The radiation efficiency of the dipole versus frequency is presented in Figure 6-6 for several values of conductor diameter d . Well below values of $ka = 0.5$, the radiation efficiency of the small dipole remains in excess of 90 percent for conductor diameters larger than 0.5 mm. It is not until the value of ka is much less than 0.5 that the radiation efficiency of the small dipole diminishes to values where it rapidly approaches 0. This illustrates that reasonably high values of radiation efficiency can be achieved with an electrically small antenna provided the physical constraints allow the use of a suitable diameter conductor.*

In low-frequency applications ($f \leq 3000$ MHz), where electrically small antennas are more typically used, high radiation efficiencies can be achieved at small values of ka . In these applications, the overall or realized efficiency of the small antenna is diminished significantly by the mismatch loss associated with the antenna's high VSWR. From a practical perspective, the first significant design challenge in using an electrically small antenna is

* It is an important point to note here that the radiation efficiency of the dipole (or any small antenna) does not scale with ka (frequency). If the frequency, length, and diameter of the dipole (antenna) are simultaneously scaled, the radiation efficiency will not remain the same as a function of ka . This is addressed in more detail in Section 6.5.

improving its VSWR by matching the antenna to the feeder transmission line. Often the impedance matching process is itself inefficient, particularly if low Q (lossy) circuit elements are used to match the antenna. Losses within the matching network further reduce the realized efficiency of the small antenna.

A similar discussion on impedance and efficiency holds for the circular loop antenna, also depicted in Figure 6-3. A circular loop antenna, having a circumference C , exhibits its first natural resonance [$X_A(\omega_0) = 0$] at an approximate radian frequency $\omega_0 \approx c\pi/C$. This first natural resonance is a parallel resonance or antiresonance, where the frequency derivative of the feedpoint reactance at the antiresonant frequency [$X'(\omega_0)$] is less than zero. At its antiresonant frequency, the loop's resistance can be several thousand ohms, and the loop essentially behaves as an open circuit. All antennas, over some ranges of frequency, exhibit antiresonant behavior where $X'(\omega_0) < 0$ and the antenna does not obey the Foster reactance theorem.¹¹

At this point, several choices of loop circumference could be considered. A circular loop antenna with a circumference $C = 1$ m could be considered, in which case the conductor length would be the same as that of the small dipole. This loop would have a diameter equal to $1/\pi$ and would therefore occupy substantially less overall volume than the 1-m dipole. The first natural antiresonant frequency of this loop (≈ 140 MHz, for $d = 5$ mm) would nearly equal the first natural series resonant frequency of the dipole. The frequency at which $ka = 0.5$ (149.9 MHz) is approximately equal to the natural antiresonant frequency of the loop, substantially higher than the frequency at which $ka = 0.5$ for the dipole. For this reason, a loop having a diameter equal to 1 m is considered, so that the loop and dipole occupy the same overall volume and the frequencies at which $ka = 0.5$ for each are identical. The circumference of the loop is equal to 3.14 (π) m, and its first natural antiresonant frequency is approximately 45 MHz, which is substantially less than the first resonant frequency of the dipole as a result of its much longer conductor length.

The impedance of a lossy circular loop antenna having a circumference $C = 3.14$ m and a conductor diameter $d = 5$ mm is depicted in Figure 6-7 over a frequency range of 5 through 150 MHz. Below the first natural antiresonant frequency, the circular loop's feedpoint reactance is always positive (inductive) and approaches 0 as $\omega \rightarrow 0$. The radiation resistance of the loop also approaches 0 as $\omega \rightarrow 0$. At DC, the loop is a short circuit.

FIGURE 6-7 Impedance of the circular loop antenna having a circumference of 3.14 m and a conductor diameter of 5 mm

At frequencies near and below the small antenna limit ($ka \leq 0.5$), the radiation resistance of the loop is approximately given by⁹

$$R_r^l \approx 20\pi^2 N^2 \left(\frac{C}{\lambda} \right)^4 \quad (6-9)$$

where N is the number of total turns in the loop. The low-frequency behavior of the loop is substantially different from the low-frequency behavior of the dipole. While the dipole's radiation resistance exhibits an ω^2 behavior, the loop's radiation resistance exhibits an ω^4 behavior. This behavior has significant impact on the loop's efficiency and bandwidth properties at small values of ka . Similar to the dipole, the loop's decreasing value of radiation resistance results in very high values of VSWR at low frequencies, making it impractical to deliver power to the loop with typical transmission lines.

As with the dipole, calculating the radiation and realized efficiency of the small loop requires determining its loss resistance. If the skin depth δ in the conductor is somewhat less than $d/2$, the loss resistance of the circular loop can be approximated as¹⁰

$$R_l^l \approx \frac{NC\rho}{\pi d\delta} \approx \frac{NC}{\pi d} \sqrt{\frac{kc\mu_0\rho}{2}} \quad (6-10)$$

For δ somewhat greater than $d/2$, the loss resistance of the small circular loop can be approximated by $R_l^l \approx 4NC\rho/\pi\rho^2$. It is assumed that the current does not vary around the loop and the current density decays exponentially from its value at the surface of the conductor.

The radiation efficiency of the loop versus frequency is presented in Figure 6-8 for a conductor diameter of 5 mm. For values of ka at and just below 0.5 ($f \leq 47.7$ MHz), the radiation efficiency of the small loop remains in excess of 90 percent. However, with decreasing values of ka , the radiation efficiency of the loop diminishes and approaches 0 at a rate much quicker than that of the dipole due to the ω^4 dependence of the loop's radiation resistance.

FIGURE 6-8 Radiation efficiency of the circular loop antenna having a circumference of 3.14 m (a diameter of 1 m) and a conductor diameter $d = 5$ mm

FIGURE 6-9 θ -sweep plane radiation pattern of the circular loop antenna having a circumference of 3.14 m (a diameter of 1 m) and a conductor diameter $d = 5$ mm at frequencies of (a) 47.7 MHz and (b) 7 MHz

At very small values of ka , a small loop is substantially less efficient than a dipole having the same conductor diameter and occupying the same overall volume. This difference in radiation efficiency for small values of ka causes the loop's quality factor and bandwidth properties to be substantially different from those of the small dipole. This will be discussed in detail in the next section.

A final point to note regarding the loop's radiation efficiency is that it can be increased by increasing the number of turns in the loop. As the number of turns increases, the loop's radiation resistance increases as N^2 while the loop's loss resistance increases as N .

The final performance properties of the small dipole and loop considered in this section are the directivity and radiation patterns, which help to describe the fundamental operating mode of the antenna. The straight-wire dipole antenna operates in a fundamental TM (electric dipole) mode from frequencies where $ka \ll 0.5$ through its first natural resonance. Throughout this entire range of frequencies, its radiation pattern is the well-known omnidirectional figure-eight. At its first natural resonant frequency, the directivity of the dipole is approximately 1.64 (2.14 dB).^{*} As the value of ka decreases, the directivity of the dipole approaches a constant value of approximately 1.5 (1.76 dB). For the 1-m dipole having a conductor diameter of 5 mm, the directivity approaches the 1.76-dB value at a frequency just below the frequency where $ka = 0.5$.

The small circular loop antenna is generally presumed to operate in a fundamental TE mode, where it behaves equivalently to a magnetic dipole. Unlike the electric dipole, however, the radiation pattern (mode) of the small loop changes significantly from frequencies where $ka \ll 0.5$ through frequencies where ka approaches 0.5, and the loop operates near its first natural antiresonance. For the loop to operate in a fundamental TE (magnetic dipole) mode, the current distribution around the loop must be nearly constant. This occurs in regions where $ka \ll 0.5$. The radiation pattern of the circular loop antenna at $ka = 0.5$ (47.7 MHz) is presented in Figure 6-9a. The loop lies in the xy plane, and the radiation

^{*} The directivity of the half-wavelength dipole (which is not naturally resonant) is slightly higher, having a value that approaches 2.18 dB.

pattern is an elevation (θ) sweep. At this frequency the loop does not exhibit the radiation pattern of a magnetic dipole, where well-developed nulls should exist in the $\pm z$ -axis directions. The directivity at this frequency is less than expected for a small antenna operating in its fundamental mode. The directivity is approximately 1.4 dB.

With decreasing values of ka , the current distribution on the loop becomes constant, and well-developed pattern nulls in the $\pm z$ -axis directions are formed. For the circular loop considered here, the TE (magnetic dipole) mode develops at frequencies where $ka < 0.1$ (≈ 10 MHz). The radiation pattern of the circular loop antenna at a frequency of 7 MHz is presented in Figure 6-9b. At this frequency the directivity approaches a constant value of approximately 1.5 (1.76 dB). The radiation efficiency of the loop in this frequency range is low, and the loop is an inefficient radiator.

6.4 POWER FACTOR, QUALITY FACTOR, AND BANDWIDTH

Wheeler introduced the concept of radiation power factor³ to quantify the radiation of real power from a small antenna that accepts a much larger value of reactive power. The power factor for small electric (dipole/capacitive) and magnetic (loop/inductive) antennas is defined in terms of equivalent circuit parameters (R , L , G , and C), depicted in Figure 6-10, and an equivalent cylindrical volume. Wheeler later provided further definition of radiation power factor in terms of the antenna's effective volume and in terms of the antenna's resistance and reactance properties. Wheeler also defined power factor as the inverse of the antenna's quality factor (Q).

The radiation power factor, P , is defined for electric and magnetic antennas in terms of their equivalent circuit parameters as

$$P_e = \frac{G_e}{\omega C}; \quad P_m = \frac{R_m}{\omega L} \quad (6-11)$$

where G_e , R_m , C , and L represent the parameters of the equivalent circuits depicted in Figure 6-10. Both P_e and P_m can be expressed in terms of the small antenna's feedpoint resistance and reactance as

$$P = \frac{R_A}{|X_A|} \quad (6-12)$$

Small Electric Antenna

Small Magnetic Antenna

FIGURE 6-10 Depictions of Wheeler's equivalent circuits for the small electric and magnetic antennas

For a lossless, electrically small antenna, both P_e and P_m exhibit an ω^3 dependence. The radiation power factor is also defined in terms of the spherical radius of the antenna's effective volume, a' , as

$$P = \frac{2}{9} (ka')^3 \quad (6-13)$$

which also exhibits an ω^3 dependence. The maximum power factor attainable for any antenna occupying a physical volume of spherical radius a is given by

$$P_{\max} = (ka)^3 \quad (6-14)$$

which implies that the maximum achievable effective volume is $1.651a$ for an antenna occupying a physical volume of spherical radius a . The significance of Eq. 6-14 is that it establishes an upper bound on the achievable power factor as a function of the antenna's size relative to the operating wavelength. Given the inverse relation between power and quality factor, Eq. 6-14 also establishes a lower bound on Q as a function of the antenna's size.

The Q and bandwidth are defined for the tuned or self-resonant small antenna. A tuned antenna is one whose feedpoint reactance is tuned to zero at a frequency ω_0 using a lossless, single component (inductor or capacitor), series tuning circuit, having a reactance of $X_S(\omega_0) = -X_A(\omega_0)$. The tuned antenna's impedance is defined as $Z_0(\omega) = R_0(\omega) + jX_0(\omega) = R_A(\omega) + j[X_S(\omega) + X_A(\omega)]$ and $Z_0(\omega_0) = R_A(\omega_0)$. The quality factor of the tuned antenna, $Q(\omega_0)$, is defined in terms of the ratio of internal energy, $W(\omega_0)$, and accepted power, $P_A(\omega_0)$, as^{12,13}

$$Q(\omega_0) = \frac{\omega_0 |W(\omega_0)|}{P_A(\omega_0)} \quad (6-15)$$

which has been shown to be approximately equal to¹³

$$Q(\omega_0) \approx Q_Z(\omega_0) = \frac{\omega_0}{2R_A(\omega_0)} \sqrt{R_A'(\omega_0)^2 + \left(X_A'(\omega_0) + \frac{|X_A(\omega_0)|}{\omega_0} \right)^2} \quad (6-16)$$

In a communication system, engineers are generally more concerned with defining and characterizing the antenna's operating bandwidth. This might lead you to question the necessity of characterizing the antenna's Q . The Q of the small antenna is characterized for two significant reasons. First, the bandwidth of an antenna is often ambiguously defined. Bandwidth may be defined in terms of the conductance bandwidth or the VSWR bandwidth for an arbitrary choice of VSWR and an arbitrary choice of feeder transmission-line characteristic impedance, Z_{CH} . Second, and more importantly, fundamental limits on the minimum achievable Q (the lower bound) can be defined in terms of the antenna's size relative to the operating wavelength (ka). Characterizing the antenna's Q allows you to quantify how well the antenna performs relative to theoretical limits. Third, if an inverse relationship between bandwidth and Q is established, a fundamental limit on the maximum achievable bandwidth in terms of the antenna's size relative to the operating wavelength can be defined.

For these reasons, it is necessary to define a bandwidth that is related to the inverse of Q over a wide range of frequencies. A suitable definition of bandwidth for this purpose

is matched VSWR bandwidth,* $\text{FBW}_V(\omega_0)$, where the VSWR (denoted by s) of the tuned antenna is determined under the condition that the characteristic impedance, Z_{CH} , of the transmission line connecting the antenna to the matched source is equal to the antenna's feedpoint resistance at the tuned frequency: $Z_{\text{CH}} = R_a(\omega_0)$. Matched VSWR bandwidth is equal to

$$\text{FBW}_V(\omega_0) = \frac{\omega_+ - \omega_-}{\omega_0} \quad (6-17)$$

where ω_+ and ω_- are the frequencies above and below ω_0 , respectively, where the VSWR is equal to s . Matched VSWR bandwidth and Q are related as¹³

$$Q(\omega_0) = \frac{2\sqrt{\beta}}{\text{FBW}_V(\omega_0)}, \quad \sqrt{\beta} = \frac{s-1}{2\sqrt{s}} \leq 1 \quad (6-18)$$

The approximations in Eq. 6-16 and Eq. 6-18 were derived in Yaghjian and Best¹³ under the assumptions that the half-power matched VSWR bandwidth ($s = 5.828:1$) of the antenna is not too large and that the antenna exhibits a single resonance within its defined operating bandwidth. In some instances where the antenna exhibits multiple, very closely spaced resonances within its operating bandwidth and $R_A'(\omega)$ and $X_A'(\omega)$ approach 0, these approximations may not hold.

The lower bound on Q , often referred to as the *Chu limit*, is given by^{12,14}

$$Q_{lb} = \eta_r \left(\frac{1}{(ka)^3} + \frac{1}{ka} \right) \quad (6-19)$$

For values of ka less than 0.5 (0.34), Eq. 6-19 is within 20 percent (10 percent) of the inverse of the upper bound on radiation power factor stated in Eq. 6-14. A significant point to note is that the Q of an electrically small antenna is often incorrectly assumed or stated to be equal to this lower bound. The Q of all electrically small antennas will be greater than this lower bound.

From Eq. 6-18 and Eq. 6-19, an upper bound on the maximum achievable matched VSWR bandwidth can be defined in terms of the antenna's size relative to the operating wavelength (ka). This upper bound is given by

$$\text{FBW}_{\text{Vub}} = \frac{1}{\eta_r} \frac{2\sqrt{\beta}(ka)^3}{1+(ka)^2} = \frac{1}{\eta_r} \frac{(ka)^3}{1+(ka)^2} \frac{s-1}{\sqrt{s}} \quad (6-20)$$

This upper bound is defined at the antenna's feedpoint terminal and does not account for any realized increase in bandwidth that may occur through the use of external matching components. Additionally this upper bound is defined for a matched antenna ($s = 1$ at ω_0). It is well known that an increase in realized bandwidth can be achieved if the antenna is not perfectly matched at the tuned or self-resonant frequency.

* Often conductance bandwidth is related to the inverse of Q . *Conductance bandwidth* is defined as the accepted power bandwidth (typically the half-power bandwidth) of the antenna under the condition that the antenna's feedpoint voltage is held constant versus frequency. This definition of bandwidth is valid provided that the tuned antenna operates in a resonance region where $X_A'(\omega_0) > 0$. If the tuned antenna is operated in an antiresonance region where $X_A'(\omega_0) < 0$, the conductance bandwidth cannot be defined. The matched VSWR bandwidth can be defined in all ranges of frequency, including regions of both resonance and antiresonance.

FIGURE 6-11 Q of the small, lossy, straight-wire dipole antenna and the lower bound on Q for the lossless dipole. The dipole has a length $l = 1$ m and a conductor diameter $d = 5$ mm.

The Q of the small dipole ($l = 1$ m) is determined using Eq. 6-16 for the various values of conductor diameter d : 5 mm, 1 mm, 0.5 mm, and 0.1 mm. The Q 's of the lossy dipoles are compared with the lower bound on Q in Figure 6-11. The lower bound is presented for the lossless dipole since the lower bound for the lossy dipoles differs as a function of the dipoles' radiation efficiencies. From Figure 6-11, the substantial difference between the dipole's actual Q 's and the lower bound is evident. The Q 's of all the dipoles are substantially higher than the lower bound. Note that the lower bound for the lossy antennas is less than the lower bound for the lossless antenna. While the lower bound exhibits a $1/\omega^3$ frequency dependence, the actual Q 's of the small dipoles exhibit a $1/\omega^4$ or $1/\omega^5$ dependence. Similar behavior is also exhibited by the lossless dipole.

Since electrically small antennas exhibit behavior that can be generally described in terms of equivalent circuit elements, the Q of the small antenna is often approximated by the value of $|X_A|/R_A$. In Figure 6-12 the Q of the 5-mm-diameter dipole is compared with the corresponding values of $|X_A|/R_A$ as a function of frequency. For $ka < 0.5$, where Q is typically very large, the value of $|X_A|/R_A$ provides a reasonable approximation of the antenna Q . At $ka = 0.5$, the value of Q is approximately 206 and the value of $|X_A|/R_A$ is approximately 187. With increasing values of ka and decreasing value of Q , the validity of the approximation degrades significantly. This is also true for electrically small antennas that are designed to be self-resonant where $X_A(\omega_0) = 0$ and $|X_A|/R_A = 0$, implying a zero Q , which is not a valid result. There is no such thing as a zero Q electrically small antenna. The values of $|X_A|/R_A$ must be used judiciously in approximating the value of antenna Q .

The behavior of the lossy loop antenna is substantially different from that of the lossy dipole antenna at small values of ka . The difference in their relative behavior is a function of the difference in the two antennas' radiation efficiencies. This difference is a result of the ω^2 frequency dependence of the small dipole's radiation resistance and the ω^4 frequency dependence of the small loop's radiation resistance. The loss resistances of both the small dipole and loop are proportional to the conductor length, inversely proportional to the conductor diameter, and exhibit an ω^2 dependence.

FIGURE 6-12 A comparison of the small dipole's Q and the value of $|X_A|/R_A$. The dipole has a length $l = 1$ m and a conductor diameter $d = 5$ mm.

The Q of the lossy circular loop ($C = 3.14$ m, $d = 5$ mm) is compared with the corresponding values of $|X_A|/R_A$ and the lower bound on Q in Figure 6-13. In this instance, the lower bound is presented for the lossy antenna. In frequency ranges where $ka \ll 0.5$ and the loop behaves as a magnetic dipole, the substantially decreasing radiation efficiency of the loop dominates its performance. At low frequencies, the Q of the loop is substantially

FIGURE 6-13 A comparison of the small loop's Q and the value of $|X_A|/R_A$. The lower bound on Q for the lossy loop is also presented. The loop has a circumference $C = 3.14$ m and a conductor diameter $d = 5$ mm.

larger than the lower bound, but neither obeys a $1/\omega^n$ dependence.* You must be cautious in measuring the bandwidth of the very small loop ($ka \ll 0.5$) and interpreting its relation to the lower bound on Q . The bandwidth of the very small loop can increase with decreasing frequency, which is consistent with the lower bound for the lossless loop as is evident in Figure 6-13. In this frequency region the increase in bandwidth is coupled with a substantial decrease in radiation efficiency.

6.5 RADIATION EFFICIENCY AND REALIZED GAIN

Considering that there is a fundamental lower bound on the minimum achievable Q as a function of antenna size relative to the operating wavelength, you might assume that there is also a fundamental limit on the maximum realized gain that can be achieved as a function of antenna size. In fact, there is not, and the maximum theoretical gain that can be achieved by the electrically small antenna is its directivity. In practice, the antenna's realized gain is of course limited by the antenna's radiation and matching efficiencies. Any small antenna can be impedance matched to the source at any single frequency. The bandwidth of the impedance match is defined by the inverse of Q and is generally limited by the frequency dependent VSWR (mismatch loss) rather than the frequency dependent radiation efficiency. Finally, if the antenna is impedance matched using an external matching network, the ohmic losses within the matching circuit must be included in the determination of the antenna's realized gain.

From Figure 6-6, it is evident that the small dipole can exhibit very high radiation efficiencies given an appropriate choice of conductor diameter. At $ka \approx 0.229$ (21.85 MHz), the radiation efficiency of the dipole is approximately 97.6 percent for a conductor diameter of 5 mm. However, the impedance of the dipole at this frequency is $1.02 - j2209 \Omega$, and the dipole's realized gain in a $50\text{-}\Omega$ system is approximately -42 dBi , which is primarily a result of the very high mismatch loss.

In previous editions of this *Handbook*, Wheeler discussed the relationship between radiation power factor and antenna gain. He stated that the operating efficiency (the realized gain) of the small antenna is limited by its radiation power factor (or the inverse of Q). He also stated that in general, greater size yields greater efficiency and that a specified efficiency imposes a requirement of some size. These statements must be interpreted judiciously in that you should not conclude that there is a fundamental relationship between realized gain and the antenna's power factor (or the inverse of Q) and size (ka). As the value of ka decreases and there is a corresponding decrease in the maximum achievable power factor and minimum achievable Q , there is not a corresponding decrease in the maximum achievable realized gain.

In stating that the operating efficiency of the small antenna is limited by its radiation power factor, Wheeler assumed the presence of an external matching network that would be necessary to match the small antenna to some desired characteristic impedance. With a small value of radiation power factor, the small antenna would have a low resistance and correspondingly much higher reactance. When matching a small antenna with a lossy network, greater matching efficiency can be achieved by increasing the value of the antenna's resistance and decreasing the value of the antenna's reactance: a higher power factor. In this context, greater operating efficiency can be achieved with a higher radiation power factor. However, concluding that a direct relation between realized gain and power factor

* The Q of the lossless loop will always increase with decreasing frequency, and it will obey a $1/\omega^n$ dependence.

or Q holds in all cases or that power factor, Q , or antenna size (ka) limits the achievable radiation efficiency or realized gain would be a mistake.

Reconsider the dipole antenna having a realized gain of -42 dBi at 21.85 MHz ($ka \approx 0.229$). At this frequency, the dipole's Q is 2195, which is approximately 25 times the lower bound of 87.7. While there is substantial margin for improving the antenna's Q , only marginal improvement can be achieved in terms of increasing the dipole's radiation efficiency. Very often, techniques used to lower the antenna Q result in a decrease in radiation efficiency. Similarly, an increase in radiation power factor does not always directly correspond to an increase in radiation efficiency. The radiation power factor of the dipole is approximately 4.64×10^{-4} .

The small dipole can be impedance matched to 50Ω using an external matching network comprised of a series inductor and a parallel inductor. Assuming that these lossy matching inductors have Q 's of 150,^{*} the values of inductances necessary to match the dipole to 50Ω ($s = 1.043$) are series inductance = $15.915 \mu\text{H}$ and parallel inductance = $0.251 \mu\text{H}$. The total matching efficiency of this network (reflection + loss) is approximately 6.48 percent, and the realized gain of the antenna is increased from -42 dBi to -10.27 dBi.

The question to consider is how much can the realized gain of the small antenna be increased through judicious antenna design. With the series and parallel inductor matching circuit, there is substantial ohmic loss within the series inductor that is used to make the small dipole nearly resonant.^{**} The same matching effect achieved with the lumped series inductor at the feedpoint can be implemented by adding more conductor length to the dipole and then winding it into a coil so as to maintain the same overall antenna length, l . This configuration is the well-known normal mode helix antenna.^{4,15} Incorporating series inductance within the antenna structure is generally more efficient than using a lumped series matching inductor at the feedpoint.

An example of a normal mode helix antenna, designed to be self-resonant near 21.5 MHz, is depicted in Figure 6-14. This normal mode helix has an overall length of 1 m and is self-resonant at a frequency of 21.46 MHz with a total feedpoint resistance of 2.87Ω and a radiation efficiency of 79.1 percent. The conductor diameter is 5 mm. This antenna can be impedance matched to 50Ω using a parallel inductor ($L = 0.091 \mu\text{H}$; $Q = 150$) at the feedpoint, which reduces the realized efficiency and gain to 76.96 percent and $+0.63$ dBi, respectively. The match frequency is 21.37 MHz, slightly lower than the resonant frequency of 21.46 MHz. The gain of the antenna is within 1.16 dB of its directivity at $ka = 0.224$.

FIGURE 6-14 Depiction of the normal mode helix antenna having an overall length of 1 m and a conductor diameter of 5 mm. The resonant frequency of the antenna is 21.46 MHz.

^{*} For lumped circuit elements, Q is primarily used to characterize the efficiency of the element. The Q of the lumped circuit element is given by the ratio of the element's reactance to its resistance, $|X|/R$, where R represents total ohmic loss. A high Q is desirable since it indicates that the circuit element has low ohmic loss and is more efficient. For antennas, the resistance (R_A) represents the total power dissipation associated with both radiation and loss. A high radiation resistance is acceptable, and a low Q is desirable since it implies high bandwidth. For the lumped circuit element, a lower Q also indicates relatively wider bandwidth. The trade-off between bandwidth and loss is relevant for both the lumped circuit element and antenna.

^{**} In using a series parallel inductor combination to match a highly capacitive small antenna, the series inductor is used to reduce (tune) the high feedpoint capacitance at a frequency where the antenna is nearly resonant (the impedance has a small value of capacitive reactance). The parallel inductor is then used to transform the impedance to 50Ω .

FIGURE 6-15 The VSWR and radiation efficiency of the small normal mode helix antenna. The VSWR is calculated assuming that the characteristic impedance of the feeder transmission line is equal to the antenna's resistance at the resonant frequency of 21.46 MHz.

The same normal mode helix is also inherently matched to a characteristic impedance of $2.87\ \Omega$ at its self-resonant frequency. In a $2.87\text{-}\Omega$ system, the antenna does not require further impedance matching, and it has a realized gain of approximately +0.75 dBi. A comparison of VSWR (mismatch loss) and radiation efficiency is presented in Figure 6-15. The radiation efficiency maintains a near constant value over a bandwidth much wider than that defined by the mismatch loss. The operating bandwidth of the small antenna is generally limited by the antenna's mismatch loss rather than the antenna's radiation efficiency.

Also note that the realized gain of the small antenna (the mismatch loss component) can be arbitrarily changed with selection of the characteristic impedance. The power factor and Q of the antenna are both independent of the choice of characteristic impedance, and a direct relationship between the antenna's realized gain and Q cannot be established.

The Q of the normal mode helix at its resonant frequency (21.46 MHz) is approximately 462, which is approximately five times the lower bound of 92. With the normal mode helix design, a substantially lower Q is achieved, but there is a decrease in radiation efficiency relative to the straight-wire dipole. The improvement in Q (or power factor) did not translate into an improvement in radiation efficiency.

Wheeler defined both a radiation power factor (radiation Q) and a loss power factor (loss Q). The radiation and loss power factors of the small dipole at 21.85 MHz are 4.52×10^{-4} and 1.12×10^{-5} , respectively (these values are determined from $R/|X|$). The radiation efficiency of the small dipole is 97.6 percent. The radiation and loss power factors of the small normal mode helix at 21.46 MHz are 1.17×10^{-3} and 0.46×10^{-3} , respectively (these values are determined from the inverse of Q since the value of $R/|X|$ at the self-resonant frequency is undefined). The radiation efficiency of the small normal mode helix is 79.1 percent. The substantial increase in radiation power factor of the normal mode helix relative to the dipole did not translate into an increase in radiation efficiency.

The final point of discussion regarding the radiation efficiency of the small antenna is its behavior as a function of scaling the size of the small antenna with changes in frequency. The radiation efficiency of the small antenna is a function of its radiation and loss resistances as defined in Eq. 6-1. Equations 6-7 and 6-9 show that the radiation resistances of the small dipole and loop scale with l/λ and C/λ , respectively. This is an expected result—if the antenna dimensions are doubled and the frequency is halved, maintaining the same value of ka , the antenna's radiation resistance is expected to be the same. The same behavior

does not hold for the loss resistance of the small antenna. Equations 6-8 and 6-10 show that the loss resistance does not scale directly with frequency but rather changes as a function of ω^2 . For this reason, the radiation efficiency of the small antenna does not scale with frequency or ka .

For example, the small normal mode helix antenna ($l = 1$ m; $d = 5$ mm) has a radiation efficiency of 79.1 percent at $ka \approx 0.224$ (21.46 MHz). Scaling the antenna dimensions by a factor of 10 and lowering the operating frequency to 2.146 MHz (maintaining the same value of ka) results in the antenna having a radiation efficiency of 92.5 percent. Scaling the antenna dimensions by a factor of 0.01 and increasing the operating frequency to 2146 MHz results in the antenna having a radiation efficiency of 26.6 percent. If the conductor diameter is not scaled with frequency but rather held constant, the opposite effect is observed. Maintaining a constant diameter with increasing frequency can become impractical since the antenna's volume decreases and the use of large diameter conductors is not possible. Often it is more practical to achieve higher radiation efficiency at lower frequencies where the use of larger diameter conductors is more practical.

6.6 THE ELECTRICALLY SMALL RECEIVE ANTENNA

In the transmit mode, where the antenna acts as a load, the primary objective is to have the small antenna radiate as much of the available source power as possible. In the receive mode, where the antenna acts as a source, the primary objective is to deliver as much signal power as possible to the receiver while maintaining a necessary level of signal-to-noise ratio. The small receive antenna can be modeled using a Thevenin equivalent circuit, where the antenna is the source having a voltage equal to the open-circuit voltage developed at the antenna's feedpoint terminal given an incident electromagnetic wave, and having a source impedance equal to the antenna's impedance $R_A + jX_A$, which is the same as the antenna's impedance in the transmit mode.

The equivalent circuit for the small receive antenna is depicted in Figure 6-16. $V_{oc}(\omega)$ is the antenna's open-circuit voltage established by an incident electromagnetic (EM) wave having a field intensity of E (V/m).^{*} $Z_A(\omega)$ is the antenna's frequency dependent feedpoint impedance, and $Z_L(\omega) = R_L(\omega) + jX_L(\omega)$ is the impedance seen at the antenna's feedpoint looking toward the receiver, which in practice is usually a constant real value such as $50\ \Omega$. $I_L(\omega)$ and $V_L(\omega)$ are the current and voltage developed at the equivalent load impedance $Z_L(\omega)$.

Often engineers struggle with the concept of relating the antenna's physical size to its ability to capture or extract power from an incident EM wave. Other than its relationship in establishing the antenna's radiation efficiency and the impedance match to the receiver, the physical size of the antenna is not relevant to its ability for capturing power from a passing EM wave. All antennas capture RF power (P_C) from an incident EM wave as a function of

$$P_C = \frac{|E|^2}{240\pi} \eta_r (1 - |\Gamma|^2) A_e = \frac{|E|^2}{240\pi} \eta_r (1 - |\Gamma|^2) \frac{\lambda^2 D}{4\pi} \quad (6-21)$$

^{*} In the formulations that follow, we assume that $|E|$ represents a *peak* value of voltage not an *rms* value. The same is true for the current and voltage used in any circuit analysis that follows from Figure 6-16. Power density is then determined using $\frac{1}{2} |E|^2 / (120\pi)$, and power is determined using $\frac{1}{2} |I|^2 R$.

FIGURE 6-16 The Thevenin equivalent circuit of the small antenna operating in the receive mode

where P_C is the power delivered to the load impedance connected at the antenna's feedpoint terminal, Γ is the usual antenna reflection coefficient, A_e is the lossless antenna's effective area, and D is the antenna's directivity. This formula for captured power is stated with the assumption that the antenna and the incident EM wave are polarization matched, and that the load impedance connected at the antenna's terminal is a pure resistance and equal to the value of Z_{CH} used to calculate Γ . If the load connected at the antenna's terminal is complex, Eq. 6-21 becomes^{*16}

$$P_C = \frac{|E|^2}{240\pi} \eta_r \frac{(1 - |\Gamma|^2)(1 - |\Gamma_L|^2)}{|1 - \Gamma\Gamma_L|^2} \frac{\lambda^2 D}{4\pi} \quad (6-22)$$

where Γ_L is the reflection coefficient for the load impedance, Z_L . The calculation of the reflection coefficients in Eq. 6-22 is made with an arbitrary choice of real characteristic impedance, Z_{CH} . However, both must be calculated using the same value of Z_{CH} . The significance of Eq. 6-21 and Eq. 6-22 is that they indicate that the difference in captured power between a small antenna and a much larger antenna is a function of the differences in radiation efficiency, impedance match, and directivity.

To illustrate these concepts, consider two dipole antennas, one small, the other nearly $\lambda/2$ in length, where both are efficient and impedance matched to 50 Ω . The near- $\lambda/2$ antenna is a dipole with additional conductor length added at the upper and lower ends of the dipole to decrease the resonant frequency to a point where the resonant resistance is 50 Ω . The small antenna is a four-arm folded spherical helix, which is inherently matched to 50 Ω . Both antennas are depicted in Figure 6-17. The folded spherical helix antenna has an overall length of 79.16 cm and a conductor diameter of 10.71 mm. The dipole antenna has an overall length of 326.6 cm and a conductor diameter of 8.17 mm. Both antennas operate at a frequency of 29.97 MHz.

It is assumed that an EM plane wave having a field intensity of 100 V/m is incident at each antenna. The power delivered to a 50- Ω load is determined using NEC4 and Eq. 6-21. The NEC4 antenna simulations include the effects of cooper loss. Results for both antennas

^{*} With all antennas, maximum possible power capture occurs when the antenna is lossless and the load connected at the antenna feedpoint terminal is the conjugate of the antenna impedance ($Z_L = Z_A^*$). If the load impedance is complex, the calculation of the normal antenna reflection coefficient, Γ , does not provide a correct indication of the power transfer to the load and Eq. 6-21 cannot be used to calculate power capture.

FIGURE 6-17 Depictions of the short dipole and electrically small folded spherical helix antennas. The short dipole has an overall length of 326.6 cm, and the folded spherical helix has an overall length of 79.16 cm. Both antennas are self-resonant at a frequency of 29.97 MHz with a VSWR less than 1.1 on a 50- Ω characteristic impedance.

and a self-resonant straight-wire dipole are presented in Table 6-1. The straight-wire dipole has an overall length of 478.8 cm and a conductor diameter of 9.57 mm. It is evident that all of the antennas capture nearly equal values of power from the incident EM wave. The difference in captured powers is primarily attributable to the difference in the antennas' directivities.

The amount of power captured by the small antenna can also be determined using simple circuit analysis if the open-circuit voltage at the antenna's feedpoint terminal is known. From the circuit of Figure 6-16, the captured power is given by

$$P_C = \frac{1}{2} |I_L|^2 R_L \quad (6-23)$$

TABLE 6-1 Comparison of Captured (Load) Power for Small Folded Helix Antenna and Two Larger Dipole Antennas (Frequency = 29.97 MHz; Incident Field Intensity = 100 V/m)

Antenna	D (dB)	Z_A (Ω)	η_r (%)	Z_L (Ω)	P_C (Watts) (NEC4)	P_C (Watts) (6-21)
Straight-wire dipole	2.14	$72.2 + j0.99$	99.8	72.2	172.7	172.51
Short dipole	1.93	$49.12 - j1.38$	99.8	50	164.05	164.33
Folded spherical helix	1.75	$46.62 - j0.22$	98.2	50	155.6	154.98

where $|I_L| = |V_{oc}/(Z_A + Z_L)|$. The open-circuit voltage developed at the feedpoint terminal of any antenna* can be determined given the incident field intensity. The receive antenna acts as a constant power source where the open-circuit voltage developed at the feedpoint is a value such that the power delivered to a conjugate matched load is given by

$$P_{CM} = \frac{|E|^2}{240\pi} \eta_r \frac{\lambda^2 D}{4\pi} = \frac{1}{2} |I_L|^2 R_A = \frac{1}{8} \frac{|V_{oc}|^2}{R_A} \quad (6-24)$$

The open-circuit voltage is then given by

$$|V_{oc}| = |E| \left| \frac{\lambda}{\pi} \sqrt{\frac{R_r D}{120}} \right| \quad (6-25)$$

Since the open-circuit voltage can be stated as $|V_{oc}| = |E| l_e$, where l_e is the effective length of the antenna, it follows that

$$l_e = \frac{\lambda}{\pi} \sqrt{\frac{R_r D}{120}} \quad (6-26)$$

For the small dipole of length l oriented along the z -axis, having a radiation resistance given by Eq. 6-7 and a peak or maximum directivity of 1.5 that occurs at $\theta = 90^\circ$, the effective length is given by

$$l_e = \frac{l}{2} \sin \theta \quad (6-27)$$

For the small loop ($ka \ll 0.5$) of circumference C lying in the xy plane, having a radiation resistance given by Eq. 6-9 and a maximum directivity of 1.5 that occurs at $\theta = 90^\circ$, the effective length is given by

$$l_e = \frac{NC^2}{2\lambda} \sin \theta \quad (6-28)$$

A comparison of the open-circuit voltages developed at the feedpoints of the small dipole and loop antennas described in Section 6.3 is presented in Table 6-2. The open-circuit voltage is determined at a frequency of 10 MHz ($ka \ll 0.5$), assuming an incident field strength of 10 V/m. Theoretical calculations using Eq. 6-27 and Eq. 6-28 are compared with NEC4 simulations.

Electrically small loops are often used as receive antennas. If the small dipole and loop are oriented to exhibit the same polarization, have the same radiation efficiency, the same directivity, and are connected to a conjugate

TABLE 6-2 Comparison of Open-Circuit Voltages Developed at Feedpoint Terminals of Small Dipole and Loop Antennas

Antenna	$V_{oc} (V) E l_e$	$V_{oc} (V) NEC4$
Small dipole	5	4.864
Small loop	1.646	1.764

The dipole has an overall length of 1 m and a conductor diameter of 5 mm. The loop has an overall diameter of 1 m and a conductor diameter of 5 mm. The incident field strength is 10 V/m. The frequency is 10 MHz. $\theta = 90^\circ$.

* The antenna is assumed to have a single feedpoint terminal.

TABLE 6-3 Comparison of Scattering Cross-Section for Small Folded Helix Antenna and Two Larger Dipole Antennas (Frequency = 29.97 MHz)

Antenna	D (dB)	Z_A (Ω)	η_r (%)	Z_L (Ω)	Cross-Section (dBsw) (NEC4)
Straight-wire dipole	2.14	$72.2 + j0.99$	99.8	72.2	-6.74
Short dipole	1.93	$49.12 - j1.38$	99.8	50	-7.24
Folded spherical helix	1.75	$46.62 - j0.22$	98.2	50	-7.93

matched load, they will deliver exactly the same power to the load. From this perspective, there is no advantage to using one antenna relative to the other. From a practical perspective, other issues become significant, and there are some advantages associated with using a small loop rather than a small dipole.

Often, particularly in HF applications, the small loop is oriented vertically so as to receive vertical polarization. In this orientation, the loop will exhibit a bi-directional pattern providing some angular discrimination in azimuth that is unavailable with the vertically polarized small dipole. In general the small dipole will have higher radiation efficiency, but it will exhibit lower realized gain due to its higher mismatch loss (these antennas are typically used in 50- Ω systems). The small dipole exhibits a very high capacitive reactance (thousands of ohms), while the loop exhibits relatively low values of inductive reactance (tens or hundreds of ohms). In addition to its lower mismatch loss, the loop's low inductive reactance is easier to tune than the dipole's high capacitive reactance. With a loop, a relatively low loss adjustable capacitor can facilitate the tuning of the loop over a wide range of frequencies. With the dipole, a relatively lossy adjustable inductor would be needed to tune the high capacitive reactance.

In addition to using the equivalent circuit of Figure 6-16 to determine the captured power, you might consider using the circuit to determine the power scattered by the antenna (or scattering cross-section) using $P_s = \frac{1}{2} |I_L|^2 R_A$. While the Thevenin equivalent circuit can always be used to determine the power delivered to the load, it cannot always be used to determine the power scattered by the antenna (power dissipated in the source). In some instances, a Norton equivalent circuit is necessary to correctly determine scattered power. For many antennas, neither circuit can be used to determine the scattered power. While details of these concepts are beyond the scope of this chapter, it is important to consider the scattering cross-section of the small antenna relative to its much larger counterparts.

The results in Table 6-1 demonstrated that the power captured by the matched, efficient small antenna nearly equals the power captured by the much larger antenna, differing primarily as a function of the difference in antenna directivity. Similar behavior is also exhibited with the scattering cross-section of the small antenna. In general the scattering cross-section of the matched, efficient small antenna will nearly equal the scattering cross-section of the larger antenna, differing as a function of variations in directivity and residual structural scattering. A comparison of the scattering cross-section of the three antennas described in Table 6-1 is presented in Table 6-3.

6.7 THE EFFECTIVE VOLUME

Wheeler was the first to describe the fundamental relations between the performance properties of the small antenna and its occupied volume. Wheeler's discussion on the effective volume of the small antenna from the previous edition of the *Handbook* is included here in its entirety.

FIGURE 6-18 The radiation power factor in terms of volume

For any shape of small antenna of either kind (*C* or *L*), the radiation power factor at one frequency is proportional to the volume. Moreover, it is nearly equal for the two kinds if they occupy nearly equal volume.* This statement needs explanation, because their configuration differs in accordance with the properties of different materials.

Figure 6-18 shows examples of the two kinds configured to occupy the space within cylinders of equal dimensions. From familiar formulas for *C*, *L*, and radiation resistance, they have equal values of radiation power factor except for two factors (k_a , k_b), which are somewhat greater than unity. Either of these factors multiplies the volume ($V = Ab$) to give the effective volume as here defined (V').

In Figure 6-18 the effective volume is compared with the radian cube $(\lambda/2\pi)^3$. It is more logical to compare it with the volume of the radiansphere:

$$V_s = \frac{4\pi}{3} \left(\frac{\lambda}{2\pi} \right)^3 \quad (6-29)$$

Within this sphere, the stored energy or reactive power is predominant. Outside this sphere, the radiated power is predominant.

In terms of the effective volume ($V' = k_a Ab$ or $k_b Ab$ in Figure 6-18), the radiation power factor becomes

$$p = \frac{2}{9} \frac{V'}{V_s} \quad (6-30)$$

(The coefficient 2/9 reflects some properties of the near field of either antenna.) The effective volume may be stated as a sphere of radius a' :

$$V' = \frac{4\pi}{3} (a')^3 \quad p = \frac{2}{9} \left(\frac{2\pi a'}{\lambda} \right)^3 \quad a' = \frac{\lambda}{2\pi} \left(\frac{9}{2} p \right)^{\frac{1}{3}} \quad (6-31)$$

* This statement applies to the capacitive and inductive antennas described by Wheeler shortly. It does not apply to the lossless or lossy straight-wire dipole and circular-loop that occupy the same volume.

FIGURE 6-19 The spherical coil with a magnetic core

Note that a certain shape of self-resonant coil radiates equally from both C and L , so the total radiation is double that of either one. This is known as the *helix radiator of circular polarization* in the normal mode.

One theoretical case of a small antenna has the greatest radiation power factor obtainable within a spherical volume. Figure 6-19 shows such an antenna and its relation to the radiansphere (V_s). It is a spherical coil with a perfect magnetic core. The effective volume of an empty spherical coil has a shape factor $3/2$. Filling with a perfect magnetic core ($k_m = \infty$) multiplies the effective volume by three.

$$p_m = \frac{2}{9} \frac{(3)(3/2)V}{V_s} = \frac{V}{V_s} = \left(\frac{2\pi a}{\lambda}\right)^3 \quad (6-32)$$

The antenna is indicated by the shaded sphere a .

This idealized case depicts the physical meaning of the radiation power factor that cannot be exceeded. Outside the sphere occupied by the antenna, there is stored energy or reactive power that conceptually fills the radiansphere, but there is none inside the antenna sphere. The reactive power density, which is dominant in the radiation within the radiansphere, is related to the real power density, which is dominant in the radiation outside.

In a rigorous description of the electromagnetic field from a small dipole of either kind, the radiation of power in the far field is accompanied by stored energy that is located mostly in the near field (within the radiansphere). The small spherical inductor in Figure 6-19 is conceptually filled with perfect magnetic material, so there is no stored energy inside the sphere. This removes the avoidable stored energy, leaving only the unavoidable amount outside the inductor but mostly inside the radiansphere. This unavoidable stored energy is what imposes a fundamental limitation on the obtainable radiation power factor.

For any actual antenna, the effective volume and its spherical radius are

$$V' = \frac{9}{2} p V_s \quad a' = \frac{\lambda}{2\pi} \left(\frac{9}{2} p\right)^{\frac{1}{3}} \quad (6-33)$$

This volume includes any image in an adjoining ground plane regarded as integral with the antenna. It is convenient to show any antenna configuration with its sphere of effective volume drawn to scale, as a rating of its radiation power factor.

6.8 THE RADIATION SHIELD (THE WHEELER CAP)

Wheeler described an ingenious yet simple technique to measure the radiation efficiency of the small antenna. His discussion on the Wheeler Cap from the previous edition of the *Handbook* is included here in its entirety. Additional details on how to determine the small antenna's radiation efficiency using measured impedance with and without the Wheeler cap are included.

It is difficult to measure the small radiation power factor, and it is especially difficult to separate it from the loss power factor of the antenna and its tuning reactor. The radiation shield was devised to separate the two.

Figure 6-20 shows the concept of the radiation shield. Its purpose is to preserve the near field in the radiansphere while avoiding radiation farther out. Ideally it is a spherical box (of high conductivity) whose radius is $\lambda/2\pi$. Its dissipation is negligible as compared with free-space radiation.

The power factor of the tuned antenna is measured with and without the shield, to give the ratio

$$\frac{\text{Loss PF}}{\text{Loss PF} + \text{Radiation PF}} \quad (6-34)$$

From this ratio, the radiation power factor can be evaluated as a fraction of the measured total. The radiation efficiency of the antenna is given by

$$\eta_r = \frac{\text{Radiation PF}}{\text{Loss PF} + \text{Radiation PF}} \quad (6-35)$$

The radiation shield is not critical as to size or shape. A circular or square cylinder is usually convenient. It should be large enough to avoid much disturbance of the field near the antenna and small enough to avoid cavity resonance, especially in any mode excited by the antenna. If open-ended, it should be long enough to attenuate radiation outside. A small shift of antenna resonance frequency is tolerable.

With the Wheeler Cap, the impedance measurement of the tuned or self-resonant antenna in free-space provides the value of R_A . The measurement of the antenna with the

FIGURE 6-20 The radiation shield for use in measuring the radiation power factor

Wheeler Cap provides the value of R_l .^{*} If the loss resistance of the small antenna occurs in series with the radiation resistance (where $R_A > R_l$), the radiation efficiency of the antenna is found using

$$\eta_r = 1 - \frac{R_l}{R_A} \quad (6-36)$$

Equation 6-36 is valid for use with electrically small dipole antennas and electrically small loops [operating well below their first natural antiresonance ($ka \ll 0.5$)], where the loss resistance is in series with the radiation resistance.

If the loss resistance of the small antenna occurs in parallel with the radiation resistance (where $R_l > R_A$), the radiation efficiency of the antenna can be found using

$$\eta_r = 1 - \frac{R_A}{R_l} \quad (6-37)$$

Equation 6-37 is valid for use with electrically small loops (or other small antennas) operating near their antiresonant frequency where the radiation and loss resistances are in parallel. It is important when measuring (or simulating) with the Wheeler Cap that the measurements of both R_A and R_l be taken as close to their respective antiresonant frequencies as possible, where $X = 0$ in each case.

6.9 TYPICAL SMALL ANTENNAS

In this section, fundamental design approaches are described for several types of electrically small antennas. As noted previously, most if not all small antennas are derivatives of the straight-wire dipole and/or circular loop. The significant design challenge with a small antenna is impedance matching it to some characteristic impedance with wide operating bandwidth and high radiation efficiency. It was shown that small antennas can be designed to exhibit high radiation efficiency as a function of allowable volume and conductor diameter. Since the operating bandwidth of the small antenna is fundamentally limited by its overall volume, the small antenna design will reach a point where additional bandwidth cannot be realized. With all designs, there is always a trade-off that can be made between bandwidth and efficiency (gain). In general the widest bandwidth is achieved when the antenna is designed to occupy all of the available volume.

For these reasons this section primarily focuses on techniques that are used to match the small antenna to some desired characteristic impedance. A characteristic impedance of 50Ω is chosen. If the small antenna is to be connected to a device with a different characteristic impedance, 50Ω may not be the optimum design objective. The discussion that follows focuses on the basic monopole antenna since small dipole-like antennas typically have very high capacitive reactance and require more efficient tuning techniques. A monopole is chosen over the dipole since many practical antennas operate with some ground plane structure. The concepts described here apply equally to both monopoles

^{*} While the Wheeler Cap measurement of radiation efficiency can be accurate, some limitations must be considered. First, the cap must have sufficient radius so as not to disturb the near fields of the antenna. Second, losses within the cap are included in the value of R_l , which may reduce the accuracy of the measurement.

and dipoles. All of the numerical results presented in this section are obtained using EZNEC Pro.

Consider a straight-wire monopole antenna mounted over an infinite ground plane* having an overall height $h = 10$ cm and a conductor diameter $d = 1$ mm. The monopole antenna exhibits its first natural resonance at a frequency of 708.4 MHz having a total resistance of approximately 36Ω . At the frequency where $ka = 0.5$ (238.56 MHz), the monopole has an impedance $2.65 - j478.1 \Omega$ and a radiation efficiency of 98.4 percent. The approximate Q of the monopole at 238.56 MHz is 200. The height of the monopole is 0.0795λ at this frequency.

With decreasing frequency, the fixed height monopole exhibits decreasing radiation resistance, approaching half the value of Eq. 6-7 as $ka \rightarrow 0.5$ and lower. For a monopole of height h , Eq. 6-7 is rewritten as

$$R_r^m \approx 40\pi^2 \left(\frac{h}{\lambda} \right)^2 \quad (6-38)$$

To efficiently operate the small monopole in a $50\text{-}\Omega$ system, its capacitive reactance must be tuned to 0 and its input resistance must be matched to 50Ω . At low frequencies, where the monopole's height is much less than the operating wavelength, its input impedance has the form of $Z = R + jX$, where the reactance X is primarily a function of the conductor's self-inductance (L_s) and the capacitance between the conductor and the ground plane (C_G). These inductance and capacitance values are translated to the feedpoint, and the monopole's input reactance takes the form of

$$X = j \left(\omega L - \frac{1}{\omega C} \right) \quad (6-39)$$

where L and C are the values of L_s and C_G translated to the feedpoint, respectively. Given the short conductor length and geometry of the monopole, both L and C are small, and as $\omega \rightarrow 0$, the $-1/\omega C$ term dominates the behavior of the total reactance. To tune the total reactance to 0 at a given frequency ω_0 , the values of either or both of L and C can be increased.

The value of L can be increased by adding conductor length to the monopole in any geometry while maintaining the same overall height h . In adding conductor length, the objective is to increase the total series inductance at the feedpoint. Generally the most effective geometry for achieving the greatest inductance with a fixed wire length is the helical coil. Any arbitrary or defined (meander line, fractal, etc.) geometry can be used to tune the monopole's reactance to 0. Generally all other geometries require more wire length to achieve the same effective inductance that can be achieved with a helical coil of the same height and conductor diameter.

For this reason, the normal mode helix antenna, depicted in Figure 6-21a, is often used as a small antenna. The effect of the helical coil is the tuning of the monopole's capacitive reactance to 0. While the total resistance typically increases relative to that of the straight-wire monopole, it does not change substantially with the addition of conductor length to

* If the small antenna is mounted at the center of a ground plane with dimensions that are reasonably larger than the antenna, its impedance will be similar to that exhibited on the infinite ground plane. If the small antenna is mounted at the corner or edge of the ground plane, its impedance will be notably different.

FIGURE 6-21 Depictions of (a) the unmatched normal mode helix and (b) the normal mode helix matched using a shunt matching stub

the antenna.* The normal mode helix is self-resonant at a frequency of 238.64 MHz having a resonant resistance of 6.2Ω . The radiation efficiency is 89.1 percent. The overall height and conductor diameter are the same as that of the monopole antenna. The total conductor length is 48.61 cm, which is approximately 0.387λ , slightly longer than the approximate 0.25λ length of a self-resonant straight-wire monopole. Generally more total wire length is needed to achieve resonance in a compressed geometry antenna.

Impedance matching of the normal mode helix can be accomplished using a parallel matching inductor at the feedpoint as discussed in previous sections. A simple technique to implement a parallel inductor at or near the feedpoint of the antenna is to connect a shunt stub between the antenna structure and the ground plane, as illustrated in Figure 6-21b. Typically only a short length of wire is required to achieve the impedance match. Minor frequency tuning can be realized by moving the connection point along the length of the antenna conductor.

The unmatched and matched impedances of the normal mode helix are presented in Figure 6-22 for a frequency range of 230 to 240 MHz. If the stub were placed exactly at the base of the feedpoint, the antenna would have been matched at a frequency lower than 237 MHz. Moving the location of the stub connection point along the antenna structure adjusts the match frequency. It is important to note that any small antenna exhibiting impedance properties similar to those shown in Figure 6-22a can be impedance matched using a shunt stub.

In this instance, the normal mode helix is matched at 237 MHz with a VSWR of 1.03 on 50Ω . The matched normal mode helix has a realized efficiency of approximately 98 percent. The Q of the matched normal mode helix is 53.2, substantially less than the Q of the straight-wire monopole. The lower bound on Q at this frequency is 10.37.

The high capacitive reactance of the monopole antenna can also be tuned to 0 by increasing the capacitance to ground. This is easily accomplished by adding a capacitive top-hat¹⁷

* This statement assumes that the antenna has a reasonable conductor diameter and that the geometry of the antenna is constrained to a reasonably narrow cylindrical diameter so that the capacitance between the antenna and the ground plane is not significantly affected. Additionally it is assumed that when winding the conductor beginning at the feedpoint, the value of height above the ground plane increases as you move along the conductor (the total antenna height remains h , independent of how much conductor is added). Geometries where the conductor is permitted to move in any direction (away from and toward the ground plane) can achieve higher values of resistance.

FIGURE 6-22 Impedance of (a) the unmatched normal mode helix and (b) the normal mode helix matched using a shunt matching stub

to the monopole, as depicted in Figure 6-23. Figure 6-23 illustrates a capacitive top-hat implemented using a wire grid structure rather than a solid disk so that direct comparison of the NEC4 simulations can be made to the normal mode helix.

To tune the reactance of the straight-wire monopole to 0 at a frequency near 238.56 MHz, a top-hat diameter of 10.62 cm is required. The capacitive top-hat antenna is self-resonant at a frequency of 238.44 MHz with a resistance of $9.63 \, \Omega$ and a radiation efficiency of 99 percent. Both values are higher than those of the normal mode helix antenna. The Q of the antenna is 16.47, substantially lower than that of the normal mode helix and straight-wire monopole. This antenna can be impedance matched in the same manner as the normal mode helix.

In general the capacitive top-hat design is more efficient and offers lower Q than the inductively loaded designs that have increased wire length compressed into a fixed volume. Note that the value of a (the spherical radius of the antenna's occupied volume) is larger with this antenna due to the increased cylindrical diameter occupied by the top-hat. The value of a for the capacitive top-hat antenna is 11.32 cm compared with the 10 cm for the normal mode helix. The lower bound on Q for the top-hat antenna is 7.44.

FIGURE 6-23 The capacitive top-hat antenna

FIGURE 6-24 Depictions of (a) the inverted-L antenna and (b) the spiral inverted-L antenna

In the preceding paragraphs, the high capacitive reactance of a short straight-wire monopole was tuned to 0 using increased wire length or a capacitive top-hat. Each of these design approaches can be matched to $50\ \Omega$ using a parallel (shunt) matching stub. Now consider a straight-wire monopole that is naturally resonant near 238.56 MHz. This monopole has a height $h = 30.07$ cm and a conductor diameter $d = 1$ mm. The resonant resistance is approximately $36\ \Omega$. The design objective now is to reduce the height of the straight-wire monopole and to maintain high radiation efficiency and a reasonable match to $50\ \Omega$.

To reduce the height of the monopole, the conductor is folded over parallel to the ground plane as illustrated in Figure 6-24a. As the total height $h \rightarrow 0$, the monopole becomes the well-known inverted-L antenna.¹⁸ A performance summary of the antenna as a function of decreasing height is presented in Table 6-4. The total conductor length is held constant at 30.07 cm as h decreases. With decreasing values of h , there is a slight increase in resonant frequency. This is compensated for by adding an appropriate amount of length to the horizontal section of wire. More importantly, with decreasing height there is always a decrease in radiation resistance and an increase in Q . These variations are directly related to the change in $(h/\lambda)^2$.⁶

If the horizontal dimension (cylindrical diameter) of the inverted-L is too large, the conductor can be wound into a spiral as illustrated in Figure 6-24b. Any shift in resonant frequency can be corrected by adjusting the total conductor length. The total resistance of the

TABLE 6-4 Performance Properties of Reduced Height Monopole Antenna as a Function of Decreasing Height

FIGURE 6-25 Depictions of (a) the inverted-F antenna and (b) the planar inverted-F antenna

spiral configuration does not shift significantly. The spiral version of the inverted-L antenna depicted in Figure 6-24b has a total conductor length of 35.7 cm and a conductor diameter of 1 mm. The resonant frequency and resistance are 238.54 MHz and 2.8Ω , respectively.

Impedance matching the inverted-L is accomplished using the shunt stub technique that was used with the normal mode helix antenna. Placing a shunt stub near the feedpoint of the inverted-L results in the well-known inverted-F antenna¹⁸ depicted in Figure 6-25a. The conductor length and stub position are adjusted to match the antenna at approximately 238.3 MHz with a VSWR of 1.3 on 50Ω . The radiation efficiency of the inverted-F is 93.1 percent. The Q of the antenna is 52.4, substantially lower than that of a straight-wire monopole of the same height.

Often, in an attempt to improve the bandwidth of a low profile inverted-F antenna, its volume is increased by converting the upper wire conductor into a plate, as illustrated in Figure 6-25b. This configuration of an inverted-F antenna is referred to as a *planar inverted-F antenna* (PIFA). PIFAs take many forms and are commonly used in a variety of wireless communication applications and devices.¹⁹ The PIFA illustrated in Figure 6-25b has a total height of 4.37 cm and top plate dimensions of 7.3 cm by 14.6 cm. It is matched at 238.5 MHz with a VSWR of 1.24 on 50Ω and a radiation efficiency of 94.8 percent. The Q of the antenna is 47.8, slightly lower than that of the inverted-F.

It has been shown that small antennas can be designed to be reasonably efficient and matched to practical impedance values, provided there is sufficient available volume. In wireless devices, available volume is often limited, and it can be challenging to design efficient matched antennas. The design of a small antenna can be more challenging when required to operate over multiple operating bands. In many of these applications, acceptable performance is achieved by relaxing the VSWR requirements. At the end of the antenna design process, the single limiting performance characteristic for the small antenna is the maximum achievable operating bandwidth, which is fundamentally established by available volume.

7.1 INTRODUCTION

Microstrip antennas (often called *patch* antennas) are widely used in the microwave frequency region because of their simplicity and compatibility with printed-circuit technology, making them easy to manufacture either as stand-alone elements or as elements of arrays. In its simplest form a microstrip antenna consists of a patch of metal, usually rectangular or circular (though other shapes are sometimes used) on top of a grounded substrate, as shown in Figure 7-1. In this chapter the basic principles of operation are discussed, and CAD formulas are given for the microstrip antenna. The CAD formulas are fairly accurate for thin substrates and illustrate the basic principles. For thin substrates the CAD formulas may even be accurate enough for final design purposes. For thicker substrates these formulas can still be used for initial design work, with full-wave simulation tools used to complete the final design.

History

The origin of microstrip antennas apparently dates back to 1953, when Deschamps proposed the use of microstrip feed lines to feed an array of printed antenna elements.^{1,2} The printed antenna elements introduced there were not microstrip patches, but flared planar horns. The microstrip patch antenna was first introduced by Munson in a symposium paper in 1972,³ which was followed by a journal paper in 1974.⁴ These papers discussed both the wraparound microstrip antenna and the rectangular patch. Shortly after Munson's symposium paper, Howell also discussed rectangular patch antennas in another symposium paper⁵ in which he credits Munson with the basic idea by referencing a private communication. In a later journal paper, Howell introduced the circular patch as well as the circularly polarized patch antenna.⁶ Soon after the introduction of the microstrip antenna, papers appeared describing methods of analysis for these antennas, including the transmission-line model,⁷ the cavity model,⁸ and the spectral-domain method.⁹ A good review of the early history of microstrip antennas is provided in the article by Carver and Mink.¹⁰ A discussion of microstrip antennas may be found in a variety of books devoted to this type of antenna^{11–22} as well as in more general antenna books and handbooks.^{23–27}

Feed Methods

Various methods may be used to feed the microstrip antenna, as shown in Figure 7-2 for the rectangular patch. The coaxial probe feed shown in Figure 7-2a is one of the most common feeds for a stand-alone element. The inset feed in Figure 7-2b is common for array applications. The proximity-coupled feed in Figure 7-2c requires multilayer fabrication,

FIGURE 7-1 (a) Rectangular microstrip patch antenna and (b) circular microstrip patch antenna

FIGURE 7-2 Feeding methods for a microstrip antenna: (a) coaxial feed, (b) inset feed, (c) proximity-coupled feed, and (d) aperture-coupled feed

but reduces spurious radiation from the feed line. The aperture-coupled feed shown in Figure 7-2d has the advantage of eliminating feed-line radiation (at the expense of some back radiation from the aperture) and also allows for relatively thick substrates, since probe reactance is not an issue.

Advantages and Disadvantages

Microstrip antennas usually have the important advantage of being low profile, and if the substrate is thin enough, they may also be *conformable*, meaning that the substrate can be bent to fit a curved surface, making the antenna very unobtrusive. Because the lateral size of a microstrip antenna on a substrate board is typically on the order of a half wavelength in the dielectric, size considerations usually dictate that these antennas are used in the UHF frequency band or higher, up through millimeter-wave frequencies, with microwave frequency applications being the most common. The main disadvantages of microstrip antennas include potentially lower radiation efficiency compared with other antennas (although this depends significantly on the substrate permittivity and thickness) and small bandwidth. These issues are discussed further next and in Section 7.9.

Radiation Efficiency and Bandwidth

Radiation efficiency depends largely on the substrate permittivity and thickness. A substrate that has a higher permittivity or that is thicker will suffer from increased surface-wave excitation, which will lower the efficiency. (Using a foam substrate is a simple way to eliminate surface-wave excitation. Removing the substrate outside of the patch cavity will also eliminate surface-wave excitation.) On the other hand, if the substrate is too

thin, the efficiency will be low due to conductive and dielectric losses. Assuming a typical Teflon substrate ($\epsilon_r = 2.2$ with a loss tangent of 0.001) and copper for the patch and ground plane with a conductivity of 3.0×10^7 S/m, the radiation efficiency is maximum for a substrate thickness of about $0.02\lambda_0$, reaching about 90 percent. When using a foam substrate, the efficiency continuously increases with increasing substrate thickness, approaching 100 percent for thicker substrates. More information on improving efficiency may be found in Section 7.9.

The bandwidth increases with the substrate thickness and inversely with the substrate permittivity, so bandwidth is made larger by using thicker low-permittivity substrates (e.g., a thicker foam substrate) at the expense of increased lateral size and vertical thickness. For a coaxially fed microstrip antenna, the substrate thickness is limited by the inductance of the feeding coaxial probe, which increases directly with increasing substrate thickness. For a typical substrate material such as Teflon and a 50- Ω coaxial feed cable, the probe reactance will become sufficiently large when the substrate thickness is about $0.018\lambda_0$ to render the antenna nonresonant unless a matching element is used. This limits the achievable bandwidth of a simple coaxially fed microstrip antenna. For a Teflon substrate and copper conductors, the maximum bandwidth (SWR < 2) of a rectangular microstrip antenna having a typical width/length (W/L) ratio of 1.5 will be about 2.5 percent, reached when the substrate thickness is about $0.025\lambda_0$. For a typical substrate thickness of $0.01\lambda_0$, the bandwidth is about 1.5 percent.

Many specialized techniques have been developed to increase the bandwidth of a microstrip antenna. These include either using thick foam substrates along with aperture-coupled feeds to avoid the probe reactance limitation, or using capacitive elements to compensate for the probe inductance. Even further increases may be achieved by using configurations that exhibit dual or multiple resonances, including stacked resonators or antennas surrounded by parasitically coupled elements. Antennas that have special geometries may also be used to greatly increase the bandwidth. By using these techniques, bandwidths exceeding 100 percent have been achieved. Further information about bandwidth improvement may be found in Section 7.9. Broadband printed antennas are the subject of Chapter 16, where you will find much more information about broadbanding techniques.

7.2 BASIC PRINCIPLES OF OPERATION

In this section, the basic operating principles of the microstrip antenna are reviewed. The mechanism of radiation is discussed first, to understand how the microstrip antenna radiates. The modes of operation of the rectangular and circular microstrip antennas are then reviewed. This provides the foundation for the calculation of the far-field radiation patterns of the rectangular and circular microstrip antennas, the results of which are presented in Section 7.4.

Radiation Mechanism

At first glance it might seem surprising that a microstrip antenna can operate very well at all, since it consists of a horizontal electric surface current (corresponding to the patch current) suspended (via the substrate) a short distance above a ground plane. Basic image theory predicts that such a current will not radiate very well. However, the microstrip patch and the ground plane together form a resonant cavity (filled with the substrate material). The cavity is lossy, due not only to the material (conductor and dielectric) loss, but also to the (desirable) radiation into space. Neglecting material loss, the quality factor Q of the antenna is inversely proportional to the substrate thickness h , for a given substrate material, assuming the substrate

is thin. Hence the bandwidth is proportional to h . The field level inside the patch cavity at resonance from an impressed current source inside the cavity (e.g., a fixed probe current) is proportional to Q . This means that the surface current on the patch (which is mainly on the lower surface of the patch) is inversely proportional to h . This increase in the amplitude of the surface current at resonance as the substrate gets thinner exactly balances the image effect, which causes the radiation level to be reduced by a factor proportional to h (relative to the patch current radiating without the ground plane). From another point of view, the voltage at the edges of the patch (the electric field times h) for a resonant patch remains approximately independent of h as the substrate gets thinner. Hence, both the electric and magnetic current models (discussed later) predict that the radiation from the patch remains approximately independent of h as the substrate thickness decreases.

Therefore, without material losses, the patch remains a good radiator even for very small substrate thicknesses, and it is possible to obtain a good impedance match even for a very thin substrate. In the lossless case the lower limit on the substrate thickness would only be determined by the bandwidth one is willing to accept. In actuality, the Q is limited by the material losses, so for sufficiently thin substrates it becomes difficult to obtain a good impedance match (in this region the radiation efficiency will also be poor). However, even for substrates as thin as $0.005\lambda_0$ a good match may be obtained with a reasonable efficiency of around 65 percent for a typical Teflon substrate and copper conductors.

Modes of Operation

For the rectangular patch, the TM_{mn} mode has a normalized electric field that is given by

$$E_z^{mn}(x, y) = \cos\left(\frac{m\pi x}{L}\right) \cos\left(\frac{n\pi y}{W}\right) \quad (7-1)$$

The usual mode of operation for a broadside pattern is the TM_{10} mode, which has no y variation and has a length L that is approximately one-half wavelength in the dielectric. In this mode the patch essentially acts as a wide microstrip line of width W that forms a transmission-line resonator of length L . The width W is usually larger than the length L in order to increase the bandwidth (see Eq. 7-35). A ratio $W/L = 1.5$ is typical.

For the circular patch, the TM_{np} mode has a normalized electric field that is given by

$$E_z(\rho, \phi) = \cos(n\phi) \frac{J_n\left(\frac{x'_{np}\rho}{a}\right)}{J_n(x'_{np})} \quad (7-2)$$

where x'_{np} is the p^{th} root of the Bessel function $J_n'(x)$. The usual mode of operation is the TM_{11} mode with $x'_{11} = 1.8418$. This mode has the lowest resonance frequency and has a broadside pattern.

7.3 CAD MODEL FOR THE INPUT IMPEDANCE

A simple circuit model for a probe-fed patch antenna operating near resonance is shown in Figure 7-3. The patch cavity resonator is modeled as a parallel RLC circuit (tank circuit), and the inductance due to the coaxial feed probe is modeled as the series inductor L_p . A justification for this model comes from an eigenfunction analysis of the input impedance.⁸

FIGURE 7-3 CAD circuit model for the probed microstrip patch antenna

From simple circuit theory, the input impedance of the patch is then given by

$$Z_{\text{in}} = j\omega L_p + \frac{R}{1 + jQ\left(f_R - \frac{1}{f_R}\right)} \quad (7-3)$$

where the frequency ratio is defined as $f_R = f/f_0$, with f_0 being the resonance frequency of the patch cavity (the resonance frequency of the RLC circuit). This is not the same as the impedance resonance frequency of the patch (the frequency for which the input reactance is zero), denoted as f_r , due to the presence of the probe inductance. The term R represents the input resistance of the patch at the cavity resonance frequency f_0 ($f_R = 1$), at which the input resistance is a maximum. CAD formulas for L_p , f_0 , Q , and R are given in Section 7.5 for a rectangular patch and in Section 7.7 for a circular patch. At the impedance resonance frequency f_r the input resistance will be slightly lower than the maximum value R according to the approximate formula

$$R_{\text{in}} = \frac{R}{1 + \left(\frac{X_p}{R}\right)^2} \quad (7-4)$$

where $X_p = \omega_0 L_p$ is the probe reactance. The probe reactance shifts the impedance resonance up from the cavity resonance by an amount $\Delta f = f_r - f_0$ given by the approximate formula

$$\frac{\Delta f}{f_0} = (BW) \left(\frac{1}{\sqrt{2}} \right) \left(\frac{X_p}{R} \right) \quad (7-5)$$

where

$$BW = \frac{1}{\sqrt{2}Q} \quad (7-6)$$

is the bandwidth of the antenna ($\text{SWR} < 2$ definition) and Q is the total quality factor. The input impedance of the tank circuit (the second term on the right-hand side of Eq. 7-3) along with its real and imaginary parts may be written in a normalized form as

$$\bar{Z}_{\text{RLC}} = \frac{1}{1 + jx} \quad \bar{R}_{\text{RLC}} = \frac{1}{1 + x^2} \quad \bar{X}_{\text{RLC}} = \frac{-x}{1 + x^2} \quad (7-7)$$

where

$$x = Q \left(f_R - \frac{1}{f_R} \right) \approx 2Q(f_R - 1) \quad (7-8)$$

is a normalized frequency term, and the bars over the impedance symbols denote that they have been normalized by dividing the impedances by R . The equations in Eq. 7-7 predict that the input resistance reaches a maximum of $R_{in} = R$ at the frequency f_0 ($x = 0$), while the magnitude of the reactance is maximum at $x = \pm 1$, for which $X_{in} = \mp R/2$. At f_0 the input impedance of the patch is simply $Z_{in} = R + jX_p$.

Using the CAD circuit model, the input impedance is plotted versus frequency for a typical rectangular patch in Figure 7-4, using the CAD formulas for the parameters of the circuit model given in the next section. Also shown is the result from a full-wave moment-method simulation using Ansoft Designer. This patch is designed to have an input resistance of $R = 50 \Omega$ at $f_r = 1.575$ GHz. The substrate has a relative permittivity of $\epsilon_r = 2.2$, a loss tangent of 0.001, and a thickness of $h = 0.1524$ cm (60 mils). The patch has an aspect ratio of $W/L = 1.5$ so that $L = 6.255$ cm and $W = 9.383$ cm. The ground plane and patch each have a conductivity of 3.0×10^7 S/m. The feed is an SMA coax with a probe radius $a = 0.635$ mm that is located at $x_0 = 1.85$ cm and $y_0 = W/2$. The CAD and full-wave results agree well except for a slight frequency shift. Note that the impedance resonance ($X_{in} = 0$) is shifted to a slightly higher frequency than the cavity resonance (where R is maximum), as expected, and the input reactance of the patch at f_0 is about 10Ω due to the probe reactance. The difference between the maximum and minimum values of the reactance curve is about the same as the value of R , as expected from Eq. 7-7. Taking the average of the maximum and minimum reactances provides an easy way to determine the probe reactance.

For this typical substrate thickness ($h/\lambda_0 = 0.008$), the simple CAD circuit model, together with the CAD formulas in the next section, works fairly well. For thicker substrates the circuit model will lose accuracy. The model is typically useful in the range $h/\lambda_0 < 0.03$. More sophisticated input impedance models include the transmission-line model⁷ and the cavity model⁸ (which may be implemented using either the eigenfunction-expansion method or the mode-matching method). However, these models are based on the same thin-substrate approximation as are the circuit model and the CAD formulas given in the next section, so the improvement in accuracy is questionable. (One advantage of the cavity model, however, is that it accounts for the probe reactance more

FIGURE 7-4 Input impedance calculated by the CAD model and by a full-wave moment-method simulation. The results from the full-wave simulation are shown with solid lines, while those from the CAD model are shown with dashed lines.

accurately than does the simple CAD formula for X_p given in the next section, which is independent of the feed position.) For thicker substrates a full-wave simulator is recommended for maximum accuracy.

7.4 RADIATION PATTERNS

The radiation patterns of a patch may be calculated using either an electric-current model or a magnetic-current model. These models are usually derived assuming that either the electric current on the patch or the electric field at the boundary of the patch corresponds to that of the dominant patch mode for a patch with ideal (magnetic-wall) boundaries. Both models then yield the same result for the far-field pattern when applied to a patch operating at the resonance frequency of the dominant mode of the ideal cavity.²⁸ The patterns may be calculated directly for two important cases. The first case assumes that the ground plane and substrate are both infinite. In the second case the ground plane is infinite, while the substrate is truncated at the edges of the patch. In the magnetic-current model the analysis for the latter case is the same as for the former case, except that the substrate material in the radiation model is now air. The radiation patterns are given next for the rectangular and circular patches, using the magnetic-current model.

Rectangular Patch

For the rectangular patch shown in Figure 7-1, the dominant TM_{10} mode has an electric field of the form

$$E_z(x, y) = \cos\left(\frac{\pi x}{L}\right) \quad (7-9)$$

The electric surface current corresponding to this cavity field is

$$\underline{J}_s(x, y) = \hat{x} \left(\frac{-1}{j\omega\mu} \right) \left(\frac{-\pi}{L} \right) \sin\left(\frac{\pi x}{L}\right) \quad (7-10)$$

and this is the current that produces the far-field radiation according to the electric-current model. In the magnetic-current model, the equivalence principle²⁹ is used to replace the patch with a magnetic surface current at the perimeter of the patch. The magnetic current has the form

$$\underline{M}_s = \begin{cases} -\hat{y} & x = L \\ -\hat{y} & x = 0 \\ -\hat{x} \cos\left(\frac{\pi x}{L}\right) & y = W \\ \hat{x} \cos\left(\frac{\pi x}{L}\right) & y = 0 \end{cases} \quad (7-11)$$

In the magnetic-current model the edges of the patch at $x = 0, L$ are referred to as the *radiating* edges since the magnetic currents on these edges are uniform and in phase. Those at $y = 0, W$ are referred to as the *nonradiating* edges since the magnetic currents on these edges reverse direction about the center of these edges and are also 180° out of phase on the two edges, so that these edges produce little radiation. The principal planes are denoted as the E -plane ($\phi = 0^\circ$) and the H -plane ($\phi = 90^\circ$). In the principal planes the nonradiating edges do not contribute when using the magnetic-current model.

As mentioned, the far-field pattern may be calculated assuming that the substrate is infinite or truncated at the edges of the patch. For thin substrates the truncation of the substrate does not have a significant effect on the pattern except near the horizon (θ approaching 90°) in the E -plane. For an infinite substrate the pattern will tuck in and go to zero at the horizon, while for a truncated substrate the pattern will remain nonzero down to the horizon in the E -plane.

A simple way to calculate the far-field pattern is by means of reciprocity.²⁹ The far field $E_i(r, \theta, \phi)$ ($i = \theta$ or ϕ) is calculated by placing a unit-amplitude testing dipole in the far field in the direction of interest (θ or ϕ). Since the testing dipole is in the far field, this calculation reduces to that of a plane wave impinging on the grounded substrate.³⁰ Such a plane-wave reflection problem has a simple closed-form solution. For the infinite substrate case, the far-field radiation pattern of the rectangular patch is given by

$$E_{\theta}^{\text{patch}}(r, \theta, \phi) = -2Wh \left(\frac{E_0}{\eta_0} \right) \cos \phi (1 - \Gamma^{\text{TM}}(\theta)) \cos \left(k_x \frac{L}{2} \right) \text{sinc} \left(k_y \frac{W}{2} \right) \text{tanc}(k_{z1}h) \quad (7-12)$$

$$E_{\phi}^{\text{patch}}(r, \theta, \phi) = 2Wh \left(\frac{E_0}{\eta_0} \right) (\cos \theta \sin \phi) (1 - \Gamma^{\text{TE}}(\theta)) \cos \left(k_x \frac{L}{2} \right) \text{sinc} \left(k_y \frac{W}{2} \right) \text{tanc}(k_{z1}h) \quad (7-13)$$

where

$$E_0 = \left(\frac{-j\omega\mu_0}{4\pi R} \right) e^{-jk_0 R} \quad (7-14)$$

and

$$k_x = k_0 \sin \theta \cos \phi \quad (7-15)$$

$$k_y = k_0 \sin \theta \sin \phi$$

$$k_{z1} = k_0 N_1(\theta) \quad (7-16)$$

with

$$N_1(\theta) = \sqrt{\epsilon_r \mu_r - \sin^2 \theta} \quad (7-17)$$

and $\text{tanc}(x) = \tan(x)/x$, with η_0 being the intrinsic impedance of free space. In Eq. 7-14 the distance R is measured from the center of the patch. The terms Γ^{TM} and Γ^{TE} denote the TM and TE reflection coefficients as seen by a plane wave impinging from the air region on the interface between the air and substrate. For the infinite substrate model a simple calculation shows that

$$1 - \Gamma^{\text{TM}}(\theta) = \frac{2}{1 + j \left(\frac{N_1(\theta) \sec \theta}{\epsilon_r} \right) \tan(k_0 h N_1(\theta))} \quad (7-18)$$

and

$$1 - \Gamma^{\text{TE}}(\theta) = \frac{2}{1 + j \left(\frac{\mu_r \cos \theta}{N_1(\theta)} \right) \tan(k_0 h N_1(\theta))} \quad (7-19)$$

For a truncated substrate (truncated at the edges of the patch) and an infinite ground plane, the far field is given by the same Eqs. 7-12 and 7-13, except that now $\epsilon_r = 1$ and $\mu_r = 1$ are used in Eqs. 7-18 and 7-19. This also implies that $N_1(\theta) = \cos \theta$. The dimensions L and W used in Eqs. 7-12 and 7-13 are those of the original patch, however, corresponding to a resonant patch on the original substrate material (and not those of a resonant patch on an air substrate) even though air is used in Eqs. 7-18 and 7-19.

Figure 7-5 shows E - and H -plane patterns for a resonant rectangular patch on an infinite ground plane and substrate. The substrate permittivity is $\epsilon_r = 2.2$, the substrate thickness is $h/\lambda_0 = 0.02$, and the patch aspect ratio is $W/L = 1.5$. Note that the E -plane is broader than the H -plane, although in both planes the pattern tends to zero at the horizon.

Figure 7-6 shows patterns for the same antenna on a truncated substrate, where the substrate is truncated at the edges of the patch, while the ground plane remains infinite. The patterns are very similar to the infinite substrate case of Figure 7-5 except near the horizon. Near the horizon the H -plane patterns are similar, but the E -plane patterns are different. In the truncated case the E -plane pattern remains nonzero at the horizon, while the pattern tends to zero for the infinite substrate case. For the truncated substrate case the E -plane pattern will always remain nonzero at the horizon for any substrate material except air (in which case there is no difference between a truncated design and an infinite substrate design). For a patch on an air substrate the E -plane pattern will tend to zero at the horizon.

Circular Patch

The far-field patterns of a resonant circular patch are similar to those of the resonant rectangular patch on the same substrate material. The normalized field of the dominant TM_{11} mode is described by

$$E_z(\rho, \phi) = \cos(\phi) \frac{J_1\left(\frac{x'_{11}\rho}{a}\right)}{J_1(x'_{11})} \quad (7-20)$$

FIGURE 7-5 Far-field patterns of a rectangular patch on an infinite ground plane and substrate. The E -plane is shown with a solid line and the H -plane is shown with a dashed line.

FIGURE 7-6 Far-field patterns of a rectangular patch on an infinite ground plane with a truncated substrate. The E -plane is shown with a solid line and the H -plane is shown with a dashed line.

This corresponds to a magnetic current at the edge of the patch that is

$$\underline{M}_s = \hat{\phi} \cos(\phi) \quad (7-21)$$

For this mode the far-field pattern is given by

$$E_\theta(r, \theta, \phi) = \left[2\pi \frac{E_0}{\eta_0} (ah) \right] \cos \phi \tan c(k_{z1}h) J_1'(k_0 a \sin \theta) (1 - \Gamma^{\text{TM}}(\theta)) \quad (7-22)$$

$$E_\phi(r, \theta, \phi) = -2\pi \left[\frac{E_0}{\eta_0} (ah) \right] \sin \phi \tan c(k_{z1}h) J_{\text{inc}}(k_0 a \sin \theta) (1 - \Gamma^{\text{TE}}(\theta)) \cos \theta \quad (7-23)$$

where E_0 is given by Eq. 7-14 (with R measured from the center of the patch) and

$$J_{\text{inc}}(x) = \frac{J_1(x)}{x} \quad (7-24)$$

The term $N_1(\theta)$ is defined in Eq. 7-17.

As with the rectangular patch, the patterns for a truncated patch are given by the same formulas as for the infinite substrate, in this case Eqs. 7-22 and 7-23, using $\epsilon_r = 1$ and $\mu_r = 1$. The dimension a is that of the original patch, however, and not that of a resonant patch on an air substrate.

Because the patterns of the circular patch are similar to those of the rectangular patch, the patterns are omitted here.

7.5 CAD FORMULAS FOR RECTANGULAR PATCH

This section presents CAD formulas for the rectangular patch shown in Figure 7-1. All of the formulas are independent of the feed except for the input resistance formula, which assumes a coaxial feed. All of these formulas assume that the patch is operating at the resonance of the TM_{10} mode, which is the usual mode of broadside operation. These formulas have been derived in Chapter 5 of Lee.¹⁷

Resonance Frequency

A fairly simple, yet reasonably accurate formula due to Hammerstad,³¹ is

$$f_0 = \frac{c}{2(L+2\Delta L)\sqrt{\epsilon_r}} \quad (7-25)$$

where c is the speed of light in vacuum and the fringing extension added to the resonant (L) dimension is given by

$$\Delta L / h = \frac{0.412 (\epsilon_{\text{eff}} + 0.3) \left(\frac{W}{h} + 0.264 \right)}{(\epsilon_{\text{eff}} - 0.258) \left(\frac{W}{h} + 0.8 \right)} \quad (7-26)$$

with

$$\epsilon_{\text{eff}} = \frac{\epsilon_r + 1}{2} + \frac{(\epsilon_r - 1) \left(1 + 10 \frac{h}{W} \right)^{-1/2}}{2} \quad (7-27)$$

In some references ϵ_{eff} is used instead of ϵ_r in Eq. 7-25, but according to the discussion in Chapter 5 of Lee,¹⁷ using ϵ_r usually gives more accurate results.

Quality Factor

For a resonant type of antenna such as the microstrip antenna, it is common to express the physical parameters of interest in terms of the quality factor, or Q , of the antenna. The Q factor is defined as

$$Q = \omega_0 \left(\frac{U_s}{P_{\text{in}}} \right) \quad (7-28)$$

where $\omega_0 = 2\pi f_0$ is the resonance frequency in radian/s, U_s is the energy stored inside the patch cavity, and P_{in} is the average power going into the antenna, which is equal to the average power being radiated plus dissipated. A microstrip antenna has both dielectric and conductor losses, and possibly surface-wave loss as well. The surface-wave loss depends on the environment surrounding the patch. If there is a substrate that surrounds the patch and the surface-wave power launched by the antenna is gradually dissipated by an absorber, then the power launched into the surface wave by the patch is a loss. On the other hand, if the substrate is truncated so that there is no substrate beyond the perimeter of the patch, then there will be no surface-wave loss. If the substrate extends beyond the patch but then ends at some distance away, the propagating surface wave will diffract at the edge of the substrate and convert into a radiation field. In this case the surface wave power is not actually a loss, but the diffracted fields will typically result in pattern degradation.

The total quality factor is related to the component quality factors as

$$\frac{1}{Q} = \frac{1}{Q_{\text{sp}}} + \frac{1}{Q_{\text{sw}}} + \frac{1}{Q_d} + \frac{1}{Q_c} \quad (7-29)$$

where

$$Q_i = \omega_0 \left(\frac{U_s}{P_i} \right) \quad (7-30)$$

and Q_{sp} , Q_{sw} , Q_d , and Q_c denote the space-wave, surface-wave, dielectric, and conductor quality factors corresponding to the powers radiated into space, launched into the fundamental TM_0 surface-wave, dissipated by dielectric loss, and dissipated by conductor loss, respectively.

Dielectric Q If the substrate has a loss tangent denoted as $\tan \delta = \epsilon''/\epsilon'$, the dielectric Q factor is given simply by

$$Q_d = \frac{1}{\tan \delta} \quad (7-31)$$

Conductor Q If the ground plane and patch metal have surface resistances R_{sg} and R_{sp} , and R_s^{ave} denotes the average of the two, then the conductor Q factor is given by

$$Q_c = \mu_r \left(\frac{\eta_0}{2} \right) \left(\frac{k_0 h}{R_s^{ave}} \right) \quad (7-32)$$

The surface resistance is related to the conductivity of the metal σ and the skin depth δ as

$$R_s = \frac{1}{\sigma \delta} \quad (7-33)$$

with

$$\delta = \sqrt{\frac{2}{\omega \mu_0 \sigma}} \quad (7-34)$$

Space-Wave Q The Q factor that accounts for the (desired) radiation into space is given as

$$Q_{sp} = \frac{3}{16} \left(\frac{\epsilon_r}{p_r c_1} \right) \left(\frac{L_e}{W_e} \right) \left(\frac{1}{h/\lambda_0} \right) \quad (7-35)$$

where $L_e = L + 2\Delta L$ and $W_e = W + 2\Delta W$ are the effective lengths and widths of the patch, accounting for fringing. The fringing length is given by Eq. 7-26, while the fringing width is given approximately by³²

$$\Delta W = h \left(\frac{\ln 4}{\pi} \right) \quad (7-36)$$

The terms p_r and c_1 are geometry terms given by (see Chapter 5 of Lee¹⁷)

$$\begin{aligned} p_r = & 1 + \frac{a_2}{10} (k_0 W_e)^2 + (a_2^2 + 2a_4) \left(\frac{3}{560} \right) (k_0 W_e)^4 \\ & + c_2 \left(\frac{1}{5} \right) (k_0 L_e)^2 + a_2 c_2 \left(\frac{1}{70} \right) (k_0 W_e)^2 (k_0 L_e)^2 \end{aligned} \quad (7-37)$$

$$c_1 = 1 - \frac{1}{n_1^2} + \frac{2}{n_1^4} \quad (7-38)$$

where $n_1 = \sqrt{\epsilon_r \mu_r}$ is the index of refraction of the substrate. The other constants are

$$a_2 = -0.16605$$

$$a_4 = 0.00761$$

$$c_2 = -0.0914153$$

Surface-Wave Q Assuming that the substrate is infinite (or that there is an absorber to absorb the surface wave), so that surface-wave power is a loss from the antenna radiation point of view, the surface-wave excitation represents a loss mechanism, and the Q for this loss is given by

$$Q_{sw} = Q_{sp} \left(\frac{e_r^{sw}}{1 - e_r^{sw}} \right) \quad (7-39)$$

where e_r^{sw} denotes the radiation efficiency of the patch when accounting for only surface-wave loss, and not dielectric or conductor loss. That is,

$$e_r^{sw} = \frac{P_{sp}}{P_{sp} + P_{sw}} \quad (7-40)$$

where P_{sp} is the power radiated into space and P_{sw} is the power launched into the surface wave. This efficiency is well approximated by that of a unit-amplitude infinitesimal horizontal electric dipole (*hed*) on the substrate. (Unit amplitude means $I l = 1$, with the current amplitude I expressed using peak phasor notation, not rms, and the length l of the small dipole measured in meters.) Therefore this efficiency is given by the approximate expression

$$e_r^{sw} = e_r^{hed} = \frac{P_{sp}^{hed}}{P_{sp}^{hed} + P_{sw}^{hed}} \quad (7-41)$$

A calculation that is accurate for thin substrates reveals that

$$P_{sp}^{hed} = \frac{1}{\lambda_0^2} (k_0 h)^2 (80 \pi^2 \mu_r^2 c_1) \quad (7-42)$$

and

$$P_{sw}^{hed} = \frac{1}{\lambda_0^2} (k_0 h)^3 \left[60 \pi^3 \mu_r^3 \left(1 - \frac{1}{n_1^2} \right)^3 \right] \quad (7-43)$$

which results in the expression

$$e_r^{\text{sw}} = e_r^{\text{hed}} = \frac{1}{1 + (k_0 h) \left(\frac{3\pi}{4} \right) \mu_r \frac{1}{c_1} \left(1 - \frac{1}{n_1^2} \right)^3} \quad (7-44)$$

For nonmagnetic substrates, a more accurate expression that has been found by Pozar³³ for the surface-wave power of the unit-amplitude dipole is

$$P_{\text{sw}}^{\text{hed}} = \frac{\eta_0 k_0^2}{4} \frac{\epsilon_r (x_0^2 - 1)^{\frac{3}{2}}}{\epsilon_r [1 + x_1] + (k_0 h) \sqrt{x_0^2 - 1} [1 + \epsilon_r^2 x_1]} \quad (7-45)$$

where

$$x_1 = \frac{x_0^2 - 1}{\epsilon_r - x_0^2}$$

and

$$x_0 = 1 + \frac{-\epsilon_r^2 + \alpha_0 \alpha_1 + \epsilon_r \sqrt{\epsilon_r^2 - 2\alpha_0 \alpha_1 + \alpha_0^2}}{(\epsilon_r^2 - \alpha_1^2)}$$

with

$$\alpha_0 = s \tan[(k_0 h) s]$$

$$\alpha_1 = -\frac{1}{s} \left[\tan[(k_0 h) s] + \frac{(k_0 h) s}{\cos^2[(k_0 h) s]} \right]$$

and

$$s = \sqrt{\epsilon_r - 1}$$

Using Eqs. 7-45 and 7-42 in Eq. 7-40 results in an expression that is more accurate than Eq. 7-44, especially for thicker substrates.

Bandwidth

The bandwidth of the patch may be defined from the frequency limits at which the standing-wave ratio (SWR) reaches a maximum threshold, assuming that the feeding transmission line

that connects to the patch is perfectly matched at the resonance frequency (i.e., $Z_0 = R$, if we neglect the effects of the probe inductance). The bandwidth is thus defined as

$$BW = \frac{f_2 - f_1}{f_r} \quad (7-46)$$

where f_r is the impedance resonance frequency of the patch, and f_1 and f_2 are the low and high frequencies on either side of the resonance frequency at which $SWR = S$, with S being a prescribed value. The bandwidth is then

$$BW = \frac{S-1}{\sqrt{S}Q} \quad (7-47)$$

For the commonly used definition $S = 2$, we have

$$BW = \frac{1}{\sqrt{2}Q} \quad (7-48)$$

Radiation Efficiency

The radiation efficiency is the ratio of power radiated into space to the total power input to the antenna. That is,

$$e_r = \frac{P_{sp}}{P_{in}} \quad (7-49)$$

where

$$P_{in} = P_{sp} + P_{sw} + P_d + P_c \quad (7-50)$$

In terms of the Q factors,

$$e_r = \frac{Q}{Q_{sp}} \quad (7-51)$$

Input Resistance

The resistance R in the circuit model of Figure 7-3 represents the input resistance of the patch at the cavity resonance frequency f_0 where the input resistance is a maximum. An approximate expression for R is

$$R = R_{edge} \cos^2 \left(\frac{\pi x_0^e}{L_e} \right) \quad (7-52)$$

where the input resistance when fed at the edge ($x_0 = 0$) is

$$R_{edge} = \eta_0 \mu_r \left(\frac{4}{\pi} \right) \left(\frac{L_e}{W_e} \right) \left(\frac{h}{\lambda_0} Q \right) \quad (7-53)$$

The effective feed location at, $x_0^e = x_0 + \Delta L$, $y_0^e = y_0 + \Delta W$ accounts for fringing.

Probe Inductance

A simple yet reasonably accurate formula for the probe inductance L_p in the circuit model of Figure 7-3 may be found by assuming that the coaxial probe feeds an infinite parallel-plate waveguide.³⁴ A calculation then reveals that the probe reactance is given by

$$X_p = \omega L_p = \eta_0 \mu_r \left(\frac{h}{\lambda_0} \right) \left[-\gamma + \ln \left(\frac{2}{\sqrt{\mu_r \epsilon_r} k_0 a} \right) \right] \quad (7-54)$$

where $\gamma = 0.57722$ is Euler's constant. Note that the probe inductance is not independent of frequency, due to the wavenumber term that appears inside the argument of the natural logarithm function. The probe reactance is directly proportional to the substrate thickness. The probe reactance also increases as the probe radius decreases, but the reactance is not a strong function of the probe radius since the variation is logarithmic. For a typical substrate with $\epsilon_r = 2.2$ and $h = 0.1524$ cm (60 mils) and a probe radius of $a = 0.635$ mm (SMA), the probe reactance X_p at 1.575 GHz is about 11 Ω .

Directivity

The directivity of the rectangular patch (with respect to an isotropic radiator) may be approximated in closed form for thin substrates as

$$D = \left(\frac{\eta_0}{40\pi} \right) \left(\frac{1}{p_r c_1} \right) \left[\frac{\text{tanc}^2(k_0 h n_1)}{1 + \left(\frac{\mu_r}{\epsilon_r} \right) \tan^2(k_0 h n_1)} \right] \quad (7-55)$$

where

$$\text{tanc}(x) = \tan(x)/x \quad (7-56)$$

For a moderate permittivity substrate such as $\epsilon_r = 2.2$, the directivity is about 6.1 (7.8 dB) when the substrate is thin. For a high permittivity substrate such as $\epsilon_r = 10.8$, the directivity is about 3.5 (5.4 dB) when the substrate is thin.

7.6 RESULTS FOR RECTANGULAR PATCH

Results are presented here to illustrate two of the basic physical properties of the rectangular patch that were discussed earlier: bandwidth and radiation efficiency. The substrate has a relative permittivity of either 2.2 (moderate permittivity) or 10.8 (high permittivity), a loss tangent of 0.001, and the patch and ground planes both have a conductivity of 3.0×10^7 S/m. The patch is resonant with an aspect ratio of $W/L = 1.5$. The frequency is 5.0 GHz.

FIGURE 7-7 Bandwidth (percent) versus the normalized substrate thickness for a moderate permittivity substrate and a high-permittivity substrate. The solid curves are from the CAD formula, while the dots (moderate permittivity) and squares (high permittivity) are from measurements.

Figure 7-7 shows a plot of bandwidth versus normalized substrate thickness for the moderate and high permittivity substrates. The bandwidths calculated from the CAD formulas are compared with those from measurements. The CAD formula is seen to be fairly accurate over this range of substrate thickness. As predicted by the CAD formula, the bandwidth increases roughly proportional to the substrate thickness, and inversely proportional to the substrate permittivity.

Figure 7-8 shows a plot of radiation efficiency in percent versus normalized substrate thickness for the same two substrate materials. In Figure 7-8a the dielectric and conductor

FIGURE 7-8a Radiation efficiency (percent) versus the normalized substrate thickness for a moderate-permittivity substrate and a high-permittivity substrate. The radiation efficiency accounts for surface-wave loss only. The dashed curves are from the CAD formula, while the solid curves are exact values from a spectral-domain calculation.

FIGURE 7-8b Radiation efficiency (percent) versus the normalized substrate thickness for a moderate-permittivity substrate and a high-permittivity substrate. The radiation efficiency accounts for all losses. The dashed curves are from the CAD formula, while the solid curves are exact values from a spectral-domain calculation.

losses are assumed to be zero, so radiation efficiency accounts only for surface-wave loss as in Eq. 7-40, using Eq. 7-45 in the calculation.

In Figure 7-8b the total radiation efficiency is plotted, accounting for all losses. In both cases the results from the CAD formulas are compared with the exact values, obtained from a spectral-domain calculation.³⁵ The CAD formula works well for thinner substrates, but loses accuracy for thicker substrates, especially for the higher permittivity.

When dielectric and conductor losses are neglected, the efficiency approaches 100 percent for thin substrates, since surface-wave loss becomes negligible. When dielectric and conductor losses are accounted for, the efficiency reaches a maximum for a certain substrate thickness, around 0.02 free-space wavelengths, and then decreases to zero as the substrate thickness tends to zero. This can be explained by examining how the different quality factors behave versus substrate thickness. The space-wave Q is inversely proportional to the electrical thickness of the substrate, as seen from Eq. 7-35. The surface-wave Q is inversely proportional to the square of the electrical thickness of the substrate, as seen from Eqs. 7-39 and 7-44. The dielectric Q is constant and does not vary with substrate thickness. The conductor Q is proportional to the substrate thickness, as seen from Eq. 7-32. Hence, when conductor and dielectric losses are eliminated, the space-wave Q becomes dominant (the smallest) as the substrate becomes thinner. However, when losses are considered, the conductor Q eventually becomes the dominant one as the substrate becomes thinner. This means that most of the input power to the antenna goes to conductor losses instead of into radiation into space, and the efficiency becomes small.

7.7 CAD FORMULAS FOR CIRCULAR PATCH

CAD formulas for the basic properties of the circular patch are given next. These CAD formulas are derived assuming that the substrate is electrically thin. Because the properties of the circular patch are similar to those of the rectangular patch, results are omitted.

Resonance Frequency

The resonance frequency of the TM_{11} mode is given by

$$f_0 = \frac{c}{2\pi a_e \sqrt{\epsilon_r}} x'_{11} \quad (7-57)$$

where c is the speed of light in vacuum and a_e is the effective radius of the patch, given by³⁶

$$a_e = a \sqrt{1 + \frac{2h}{\pi a \epsilon_r} \left[\ln \left(\frac{\pi a}{2h} \right) + 1.7726 \right]} \quad (7-58)$$

Quality Factor

The formulas for the dielectric and conductor quality factors Q_d and Q_c are the same as for the rectangular patch and are given by Eqs. 7-31 and 7-32. The space-wave quality factor is given by

$$Q_{sp} = \frac{2x_c \left(\frac{1}{k_0 h} \right) \epsilon_r}{I_c} \quad (7-59)$$

where

$$x_c \equiv \frac{1}{x'_{11}{}^2} (x'_{11}{}^2 - 1) = 0.238695 \quad (7-60)$$

and

$$I_c \equiv \int_0^{\pi/2} C(\theta) d\theta \quad (7-61)$$

with

$$C(\theta) = \sin \theta \tan^2(k_{z1} h) \left[\left| 1 - \Gamma^{TM}(\theta) \right|^2 J_1'^2(k_0 a \sin \theta) + \left| 1 - \Gamma^{TE}(\theta) \right|^2 \cos^2 \theta J_{inc}^2(k_0 a \sin \theta) \right] \quad (7-62)$$

The terms appearing in the preceding equation are the same as those defined in Eqs. 7-56, 7-16, 7-18, 7-19, and 7-24. An approximate closed-form expression for the space-wave quality factor may be obtained for a thin substrate by approximating the integral I_c in Eq. 7-61 as

$$I_c = \frac{4}{3} p_c \quad (7-63)$$

where

$$p_c = \sum_{k=0}^6 (k_0 a)^{2k} e_{2k} \quad (7-64)$$

with the coefficients defined as

$$\begin{aligned}
 e_0 &= 1 \\
 e_2 &= -0.400000 \\
 e_4 &= 0.0785710 \\
 e_6 &= -7.27509 \times 10^{-3} \\
 e_8 &= 3.81786 \times 10^{-4} \\
 e_{10} &= -1.09839 \times 10^{-5} \\
 e_{12} &= 1.47731 \times 10^{-7}
 \end{aligned} \tag{7-65}$$

The surface-wave quality factor is given by Eqs. 7-39 and 7-41, along with 7-42 and either 7-43 (which yields Eq. 7-44) or 7-45.

Bandwidth

The bandwidth of the circular patch is given by Eqs. 7-47 and 7-48, where the total quality factor is given by Eq. 7-29, using the appropriate formulas for the quality factors of the circular patch presented in the preceding section.

Radiation Efficiency

The radiation efficiency of the circular patch is given by Eq. 7-41 together with Eq. 7-42 and either Eq. 7-43 (which yields Eq. 7-44) or 7-45.

Input Resistance

The input resistance of the circular patch fed by a coaxial feed at the frequency of the cavity resonance f_0 is

$$R_{\text{in}} \approx R_{\text{edge}} \left[\frac{J_1^2 \left(\frac{x'_{11} \rho}{a} \right)}{J_1^2(x'_{11})} \right] \tag{7-66}$$

where the feed is located at a radius ρ_0 from the center. The edge resistance is given by

$$R_{\text{edge}} = \left[\frac{h^2}{2P_{\text{sp}}} \right] e_r \tag{7-67}$$

where

$$P_{sp} = \frac{\pi}{8\eta_0} (k_0 a)^2 h^2 \int_0^{\pi/2} \text{tanc}^2(k_{z1} h) \left[|1 - \Gamma^{\text{TM}}(\theta)|^2 J_1'^2(k_0 a \sin \theta) + |1 - \Gamma^{\text{TE}}(\theta)|^2 J_{inc}^2(k_0 a \sin \theta) \cos^2 \theta \right] \sin \theta d\theta \quad (7-68)$$

In Eq. 7-67, e_r is the radiation efficiency of the circular patch and P_{sp} is the space-wave power radiated by the magnetic current in Eq. 7-21. The space-wave power may be written as

$$P_{sp} = \frac{\pi}{8\eta_0} (k_0 a)^2 h^2 I_c \quad (7-69)$$

where the integral I_c is defined in Eq. 7-61 and approximated in Eq. 7-63.

Probe Inductance

Equation 7-54 is based on a parallel-plate waveguide model, which ignores the geometry of the patch. Therefore, this formula may be used equally well for the circular patch.

Directivity

An approximate formula for the broadside directivity of the circular patch is

$$D = \frac{3 \text{tanc}^2(k_1 h)}{p_c \left[1 + \left(\frac{\mu_r}{\epsilon_r} \right) \tan^2(k_1 h) \right]} \quad (7-70)$$

where p_c is defined in Eq. 7-64 and the tanc function is defined in Eq. 7-56.

7.8 CIRCULAR POLARIZATION

Microstrip antennas are often used as elements to radiate circular polarization (CP). Circular polarization may be achieved in two ways. The first is by means of a dual feed using a square or circular patch that is fed with two feeds spaced 90° apart and fed with a 90° phase difference. The 90° phase difference may be realized using a delay line or, for a broader bandwidth phasing, a branchline hybrid.³⁶ In most cases the bandwidth of the patch is small compared with the bandwidth of the phasing, so a simple 90° delay line is adequate.

A more compact way to realize CP is through a single feed, using a nearly-square patch or an elliptical patch. The nearly-square design has length L and width W (see Figure 7-1) that are nearly, but not exactly, equal. The feed is located along the diagonal. This method of realizing CP is simple. However, the drawbacks include having a lower CP bandwidth compared with the dual-feed arrangement, and the design may be somewhat more difficult to optimize properly. Simple design formulas exist, however, to aid in the design of the patch dimensions and the feed location. This is discussed next.

It is assumed that CP is desired at broadside at a frequency f_{cp} (the axial ratio will degrade as the angle θ increases). Denote f_{0x} and f_{0y} as the cavity resonance frequencies corresponding to the dimensions L and W , respectively. The first design equation is then

$$f_{cp} = \frac{1}{2}(f_{0x} + f_{0y}) \quad (7-71)$$

which stipulates that the frequency of operation should be halfway between the two cavity resonance frequencies. The second design equation says that the difference in the two cavity resonance frequencies should be related to the Q of the patch as

$$\frac{\Delta f}{f_{cp}} = \frac{1}{Q} \quad (7-72)$$

where $\Delta f = f_{0y} - f_{0x} > 0$ for left-handed circular polarization (LHCP) and $\Delta f = f_{0x} - f_{0y} > 0$ for right-handed circular polarization (RHCP). Hence, the resonance frequencies of the patch should be chosen as

$$f_{0x} = f_{cp} \left[1 \pm \frac{1}{2Q} \right] \quad (7-73)$$

$$f_{0y} = f_{cp} \left[1 \mp \frac{1}{2Q} \right] \quad (7-74)$$

where the top sign is for RHCP and the bottom sign is for LHCP. The quality factor Q is related to the impedance bandwidth BW of the patch when it is fed along a centerline and operated as a linearly polarized patch, through Eq. 7-6. The bandwidth of the linearly polarized patch may be determined by using the CAD formulas for the quality factor given previously, or by other methods including full-wave simulation and measurements.

The input resistance at the frequency f_{cp} is given by $R = R_x = R_y$, where R_x and R_y are the resonant input resistances of the patch when fed along the centerlines at $(x_0, W/2)$ or $(L/2, y_0)$ with $x_0 = y_0$, so that the (1,0) or (0,1) modes are resonant, respectively. Hence the input resistance of the diagonal feed at f_{cp} is simply the resonant input resistance if the patch were fed along either of the two centerlines, assuming that we keep the same value of x_0 or y_0 . For example, we can determine the value of x_0 for a square patch fed along the centerline in order to have a $50\text{-}\Omega$ input resistance at resonance. The input resistance of the nearly square patch fed along the diagonal will then be $50\text{ }\Omega$ at f_{cp} provided the distance of the feed from the corner of the patch measured along the diagonal is $x_0\sqrt{2}$. At the frequency of CP operation f_{cp} the input impedance will have a small imaginary part equal to the probe reactance.

Once the frequencies f_{0x} and f_{0y} have been determined, the corresponding dimensions of the patch L and W may be determined. For example, we can use Eq. 7-25, which becomes

$$f_{0x} = \frac{c}{2(L + 2\Delta L)\sqrt{\epsilon_r}} \quad (7-75)$$

$$f_{0y} = \frac{c}{2(W + 2\Delta W)\sqrt{\epsilon_r}} \quad (7-76)$$

Because the patch is nearly square, the fringing extensions ΔL and ΔW are approximately equal. The fringing extension ΔL may be calculated approximately using Eq. 7-26.

A bandwidth of the circular polarization may be defined in terms of the axial ratio of the CP at broadside. The axial-ratio bandwidth is defined as

$$BW^{AR} = \frac{f^+ - f^-}{f_{cp}} \quad (7-77)$$

where f^+ and f^- are the frequency limits on either side of f_{cp} for which the axial ratio is $\sqrt{2}$ (3 dB). It may be shown³⁷ that the axial-ratio bandwidth is related to the quality factor of the patch as

$$BW^{AR} = \frac{0.348}{Q} \quad (7-78)$$

Comparing Eq. 7-78 with Eq. 7-6, it is seen that the axial-ratio bandwidth is smaller than the impedance bandwidth of the corresponding linearly polarized patch by a factor of about 0.49. The impedance bandwidth of the nearly square CP patch is given by³⁷

$$BW^{CP} = \frac{\sqrt{2}}{Q} \quad (7-79)$$

Comparing Eq. 7-79 with Eq. 7-6, it is seen that the impedance bandwidth of the CP patch is larger than that of the same patch operated as a linearly polarized patch by a factor of 2.

7.9 MICROSTRIP ANTENNAS WITH IMPROVED PERFORMANCE

The improvement of the basic microstrip antenna properties is a topic of considerable interest. In particular, considering the traditional limitations of microstrip antennas, the improvements of bandwidth and radiation efficiency are particularly relevant, along with reducing surface-wave excitation and lateral radiation from the patch, which results in undesirable mutual coupling and edge diffraction from the edges of the surrounding ground plane. These issues are reviewed next.

Bandwidth Improvement

The bandwidth of a microstrip antenna may be improved in several ways. First, the use of a low permittivity substrate is beneficial since bandwidth is inversely proportional to the permittivity according to Eq. 7-35, at least when the patch is operating in a region where the efficiency is high and the space-wave Q is dominant (the smallest). Second, a thicker substrate may be used since the bandwidth is proportional to the substrate thickness in the region where the space-wave Q dominates, as Eq. 7-35 again shows. For a coaxial feed, the bandwidth is limited by the fact that the probe inductance increases with increasing substrate thickness, as seen from Eq. 7-54. As mentioned in the “Introduction,” this limits

the substrate thickness to a maximum value, beyond which the coaxially fed patch will not be resonant (i.e., the input impedance will remain inductive). According to Eq. 7-7 and the discussion immediately afterward, the input reactance of the patch cavity reaches a negative minimum of $X_{\text{RLC}} = -R/2$, where R is the value of the maximum input resistance, which occurs at the cavity resonance frequency f_0 . Hence if the probe reactance exceeds $R/2$, no resonance frequency f_r can be found for which the input impedance will be real.

Various methods may be used to overcome this limitation due to the probe reactance. A capacitive element may be inserted into the coaxial feed to compensate for the probe reactance. For example, one can use a capacitive annular slot on the patch that surrounds the contact point where the probe meets the patch.³⁸ Alternatively, other feed methods may be used that avoid the probe reactance problem. For example, the aperture-coupled feed allows for the patch cavity to be excited without introducing a probe reactance, and hence a thicker substrate is possible.

Other techniques to increase bandwidth include introducing multiple resonances into the structure. This may take the form of stacked patches, coplanar parasitic patches, or patches that have novel shapes such as the *U*-shaped patch.^{19,21} Using special feed networks or feeding techniques to compensate for the natural impedance variation of the patch is another method.

Chapter 16 of this *Handbook* is concerned with wideband printed antennas, and you will find more discussion on broadbanding techniques in that chapter.

Efficiency Improvement

Surface-wave excitation increases as the permittivity of the substrate increases and as the thickness of the substrate increases (unless the substrate is air). On the other hand, if the substrate is made too thin, the radiation efficiency suffers due to increased conductor and dielectric losses, since the conductor and dielectric Q factors will become dominant (smaller than the other ones) as the substrate becomes thin, as seen from Eqs. 7-31 and 7-32. One way to overcome this trade-off is to use a low-permittivity substrate material such as foam. The foam substrate may be made thick to minimize conductor and dielectric losses, without suffering from surface-wave excitation. This has the added advantage of increasing the bandwidth. If the application allows it, the substrate may also be removed from the area outside the patch, to avoid surface-wave excitation.

Other alternatives have been developed for minimizing surface-wave excitation. The ground plane may be patterned to form a periodic structure, or a periodic structure may be printed on the substrate surrounding the patch, to form an *electromagnetic band gap* or EBG structure.³⁹ Being a periodic structure, the EBG structure has passbands and stopbands, for which modal surface-wave propagation on the structure is allowed or prohibited. In the stopband region the surface wave on the structure cannot propagate. Care must be exercised to design the EBG structure so that the stopband is omnidirectional, meaning that the surface-wave propagation is prohibited in all directions.

Reduced Surface Wave Antennas

A type of microstrip antenna called the *reduced surface wave* (RSW) antenna has been proposed.⁴⁰ The design consists of a microstrip annular ring with inner radius a and outer radius b that is short-circuited to the ground at its inner radius, as shown in Figure 7-9. The short circuit may be realized by a circular ring of shorting vias (metal posts) placed at $\rho = a$.

The antenna is operated in the TM_{11} mode, for which the magnetic current at the outer boundary corresponding to the dominant patch mode has the form of Eq. 7-21.

FIGURE 7-9 Reduced surface wave microstrip antenna

Analysis shows that the surface-wave field along the ground plane ($z = 0$) excited from such a ring of magnetic current will have the form

$$E_z^{\text{sw}}(\rho, \phi, 0) = A \cos \phi J_1'(\beta_{\text{TM}_0} b) H_1^{(2)}(\beta_{\text{TM}_0} \rho) \quad (7-80)$$

where A is an amplitude coefficient, β_{TM_0} is the wavenumber of the dominant TM_0 surface-wave mode of the grounded substrate, J_1' is the derivative of the Bessel function J_1 , and $H_1^{(2)}$ is the Hankel function of the second kind. The surface-wave field excited by this magnetic current will be zero provided that

$$\beta_{\text{TM}_0} b = x'_{11} = 1.8418 \quad (7-81)$$

To be more general, any value x'_{1p} may be used in Eq. 7-81, but using $p = 1$ gives the patch with the smallest outer radius. A normal circular patch with the critical radius b will not be resonant, as is easily seen by comparing Eq. 7-81 with Eq. 7-57, which is equivalent to Eq. 7-81 with k_1 being used instead of the wavenumber of the surface wave. A circular patch with this critical radius will be larger than resonant size. Therefore, to make the patch resonant, a short-circuit boundary is introduced at $\rho = a$ as shown in Figure 7-9. By properly selecting the inner radius a , the patch may be made resonant at the desired operating frequency for which Eq. 7-81 is satisfied. Assuming an approximate perfect magnetic wall at the outer radius, this results in the following design condition for choosing the inner radius:

$$\frac{J_1(k_1 a)}{Y_1(k_1 a)} = \frac{J_1' \left(\frac{k_1 x'_{11}}{\beta_{\text{TM}_0}} \right)}{Y_1' \left(\frac{k_1 x'_{11}}{\beta_{\text{TM}_0}} \right)} \quad (7-82)$$

where Y_1 is the Bessel function of the second kind. The location of the coaxial feed probe may be selected to obtain the desired input resistance at resonance.

If the substrate is relatively thin, the TM_0 surface wave has the property that the wavenumber is close to the wavenumber of free space. Hence we have the approximate condition that

$$k_0 b = x'_{11} = 1.8418 \quad (7-83)$$

Equation 7-83 is a condition for having zero lateral radiation from the patch, i.e., zero far-field radiation along the horizon. Hence the RSW antenna not only reduces the amount of surface-wave excitation, but it also reduces the lateral radiation that travels along the ground plane. For a thin substrate the lateral radiation is usually the more important of the two, unless the distance from the patch becomes large, but both contribute to diffraction from the edges of the ground plane. This undesirable edge diffraction results in interference with the primary pattern above the ground plane, and in nonzero radiation in the region behind the ground plane.

Equation 7-83 also implies that the diameter of the RSW antenna will be approximately $0.6\lambda_0$, independent of the substrate permittivity. That is, the RSW antenna cannot be miniaturized by using a higher substrate permittivity. This is one of the main drawbacks to the antenna. The antenna has roughly the same bandwidth as a conventional circular patch on the same substrate.

Figure 7-10a shows the calculated and measured E -plane patterns for a conventional circular patch of radius $a = 2.66$ cm operating at 2.0 GHz on a substrate with a relative permittivity of 2.94 and a thickness of 1.524 mm. The feed is at $\rho_0 = 0.61$ cm. The calculated pattern assumes an infinite ground plane and substrate, while the measurement was taken on a circular ground plane with a diameter of 1 m. The measured E -plane pattern has a significant rippling in the forward direction and has a significant amount of back radiation behind the ground plane, due to edge diffraction. This is because the surface wave and the lateral wave are both excited with a $\cos \phi$ variation, and hence the E -plane ($\phi = 0$) is the one that suffers the most from surface-wave excitation and lateral radiation. Also, the measured E -plane pattern does not agree very well with the calculated pattern, since the calculated pattern assumes an infinite ground plane and therefore neglects edge diffraction.

Figure 7-10b shows the calculated and measured E -plane patterns for an RSW antenna on the same substrate, operating at the same frequency. The dimensions are $a = 2.417$ cm and $b = 4.392$ cm, with the feed located at $\rho_0 = 2.95$ cm. It is seen that the E -plane pattern is much smoother in the forward region than for the conventional patch; also there is much less radiation in the back region behind the ground plane. Because there is less edge diffraction, the measured pattern agrees much better with the calculated pattern, which assumes an infinite ground plane and neglects edge diffraction.

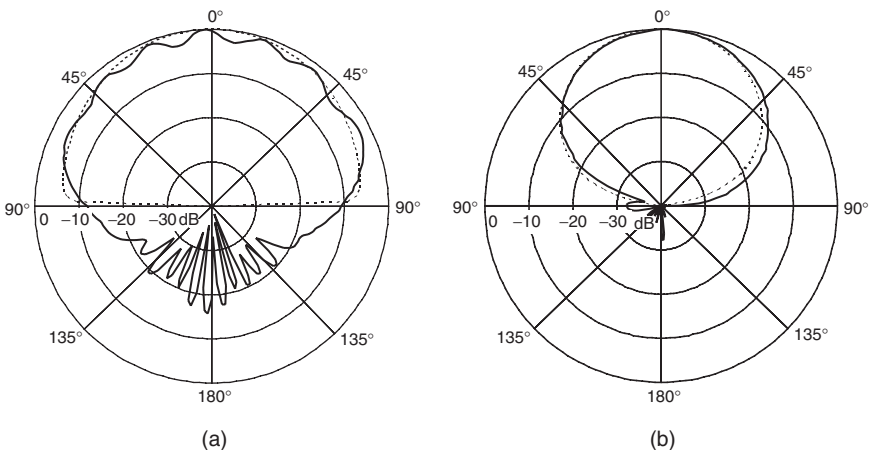

FIGURE 7-10 E -plane patterns for (a) conventional circular patch antenna (b) reduced surface wave antenna. The measured patterns are shown with solid lines, while the calculated patterns are shown with dashed lines.

As a consequence of the reduced surface-wave excitation and lateral radiation, there is also less mutual coupling between RSW antennas than between conventional microstrip antennas, at least for separations that are larger than about $0.75\lambda_0$ between centers.⁴¹ For array applications the large size of the RSW antenna limits the application of these antennas to arrays that can tolerate this larger element spacing.⁴²

8.1 INTRODUCTION

This chapter deals with the radiation characteristics of slot antennas and includes the effects of finite and curved surfaces, dielectric coatings, cavity backing, and single slots fed by waveguides. The simplest example of such an antenna consists of a rectangular slot cut in an extended thin flat sheet of metal with the slot free to radiate on both sides of this sheet, as shown in Figure 8-1. The slot is excited by a voltage source such as a balanced parallel transmission line connected to the opposite edges of the slot or a coaxial transmission line connected to the opposite edges of the slot or a coaxial transmission line.

FIGURE 8-1 Rectangular slot

The electric field distribution in the slot can be obtained from the relationship between the slot and complementary wire antennas, as established by Booker.¹ It has been shown that the electric field distribution (magnetic current) in the slot is identical to the electric current distribution on the complementary wire. In the illustrated rectangular slot, the electric field is perpendicular to the long dimension, and its amplitude vanishes at the ends of the slot.

The electric field is everywhere normal to the surface of the slot antenna except in the region of the slot itself. The theoretical analysis of this configuration shows that the radiation of the currents in the sheet can be deduced directly from the distribution of the electric field in the slot. Consequently, the radiated field of an elementary magnetic moment within the slot boundaries should include the contribution of the electric current flowing on a metal surface.

A slot-antenna design will often require that the slot be cut in something other than an extended flat sheet surface. Whatever the surface, the electric field will be normal everywhere except in the region of the slot. The field due to the electric currents on this metal surface can be deduced from the exciting magnetic currents² in the slot, just as in the case of the flat metal sheet. This field can be combined with the exciting field so that the result is the total field due to a magnetic current on the given boundary surface. Thus the field of a thin rectangular slot cut in a circular cylinder differs from that of a slot cut in a flat metal sheet because the distribution of electric currents is different for the two cases.

In general, the slot antenna is not free to radiate on both sides of the surface on which it is cut because one side is either completely enclosed, e.g., the slotted cylinder antenna, or it is desired that the radiation on one side be minimized. In these cases, the influence of the enclosed cavity region on the excitation and impedance of the slot antenna is significant to the antenna design.

8.2 SLOTTED-WAVEGUIDE ANTENNAS

Slotted-waveguide antennas have significant applications in the areas of missile, spacecraft, and airborne radar. Broad-wall slotted-waveguide antennas have been studied extensively. Oliner,³ following research by Stevenson,⁴ has derived equivalent circuit representations for this type of antenna. These circuits allow accurate computation of the normalized conductance, susceptance, resistance, reactance, and resonant frequency of broad-wall slots. The types of slots and the equivalent networks are given in Chapter 9.

Dielectric-covered broad-wall slots also have been characterized thoroughly. Bailey⁵ has summarized significant findings. The general problem discussed by Bailey extends Oliner's work to include the effects on broad-wall slots radiating into a multilayer dielectric medium. The basic effect that occurs by adding a dielectric layer over slots in a waveguide is to

FIGURE 8-2 Resonant length of a dielectric-covered shunt slot in WR-90 (RG 52/U) waveguide ($b^1 = 0.0625$ in, $t = 0.050$ in, $a = 0.900$ in, $b = 0.400$ in) (after Bailey⁵ © IEEE 1970)

produce a downward shift in resonant frequency. For dielectric layers whose thickness is greater than 0.2λ , where $\lambda = \lambda_0 \sqrt{\epsilon}$, the approximate resonant shift is given in Figure 8-2, where λ is the wavelength in the dielectric, λ_0 is the wavelength in free space, and ϵ is the dielectric constant. Further analysis, and comparison with experimental data, is also available, as shown in Figure 8-3.

FIGURE 8-3 Resonant conductance (a) and resonant length (b) versus layer thickness, $\epsilon_r = 3.31$ (after Katehi⁶ © IEEE 1990)

The typical polarization of most slotted-waveguide antennas is linear. However, several slotted-waveguide elements have been designed that produce circular polarization.^{7,8}

8.3 TAPERED AND FLARED SLOT ANTENNAS

Tapered slot antennas (TSAs) were first introduced in the late 1950s. It was then that Eberle et al⁹ produced a waveguide-fed, flared slot antenna for use in aircraft skins where conventional antennas could not be easily integrated. Gibson¹⁰ then developed the strip-line-fed, exponentially tapered slot antenna, which he called the *Vivaldi aerial*. His design was the first recognized TSA that showed symmetric *E*- and *H*-plane beamwidths, low sidelobes, and moderate gain.

Since then, with the increased interest in MIC (microwave integrated circuit) antennas for applications ranging from satellite communications to remote sensing, tapered slot antennas have been studied extensively, both empirically and theoretically. In general, the performance you can expect to achieve from a typical TSA includes

- Broadband operation
- Moderate gain
- Low sidelobes

These radiation characteristics make TSAs suitable elements for reflector feeds or as stand-alone antennas.

The current form of a typical TSA is planar in nature, etched on a thin, low-dielectric-constant microwave substrate, and fed by a stripline, finline, or slotline configuration, as shown in Figure 8-4. As a result of the typical substrates used in TSA designs, it is important to consider the possibility of the feedline itself radiating or coupling with the antenna element. Work at Harris Corporation has addressed this problem and has resulted in a bilateral stripline feed as one solution (see Figure 8-5).

TSAs are a type of traveling-wave antenna. Their operation is based on a traveling wave propagating along the surface of the antenna taper with a phase velocity less than the speed of light.¹³ Under this condition, endfire radiation results. Zucker reviews properties of traveling-wave antennas in Chapter 10.

FIGURE 8-4 Three different types of endfire tapered slot antennas along with a dielectric-rod antenna shown for comparison (after Yngvesson et al^{11,12} © IEEE 1985 and © IEEE 1989)

FIGURE 8-5 Stripline designs of the bilateral slotline-fed antenna. *Note 1:* Length of taper is proportional to gain; maximum gain approximately 10 dB. *Note 2:* Quarter wave calculated using dielectric constant of material. *Note 3:* May be narrower than 0.4 to obtain desired slotline impedance. Taper rate: $y = a^{kx}$, where $a = 0.5$ slotline width, $k = \text{constant}$, $x = \text{length of flare}$.

8.4 CAVITY-BACKED RECTANGULAR SLOT ANTENNAS

The electric field on the coaxially fed, cavity-backed rectangular slot (see Figure 8-6a) is neither sinusoidal nor complementary to a ribbon dipole antenna. This antenna is a cavity resonator, energized by the coaxial transducer, which radiates from the slot aperture. The field distribution in the slot, therefore, is dependent on the excitation of higher cavity modes as well as the principal mode (TE_{10}). The equivalent circuit of a cavity-backed slot antenna is shown in Figure 8-7b; the shunt conductance is the radiation conductance of the slot. The conductance of the cavity-backed resonant half-wave slot is half the open slot, free to radiate on both sides. That is, the shunt resistance is at least 800 rather than 400 Ω .¹⁴⁻¹⁶ The parallel susceptance shown in the equivalent circuit is the sum of the shunt susceptance of the slot radiator and the TE-mode susceptance of the cavity. The series-resonant circuit is the result of the energy stored in the TM modes in the cavity and feed structure.

FIGURE 8-6 Cavity-backed rectangular slot: (a) pictorial representation; (b) equivalent circuit

FIGURE 8-7 Cavity-backed T-bar-fed slot antenna. Typical dimensions shown in inches (millimeters) for a frequency range of 0.5 to 1.2 GHz: a , 12.00 (304.8); b , 4.00 (101.6); x , 3.25 (82.55); w , 6.75 (171.45); D , 2.25 (57.15); E , 0.75 (19.05); F , 0.63 (16.00); G , 0.19 (5.826); H , 0.25 (6.35).

To obtain the maximum radiation conductance, a sinusoidal distribution of electric field (magnetic current) must be generated. This distribution will be achieved when the energy stored in the cavity in the vicinity of the slot is primarily in the TE_{10} mode, i.e., by making the cavity dimensions big enough so that the dominant mode is above cutoff. For small cavities, edge loading, as in a highly capacitive slot, will improve the field distribution.

An important design parameter is the antenna Q , which is minimum when the stored energy is only in the dominant mode. The Q limits the inverse voltage-standing-wave-ratio (VSWR) bandwidth product; for a small cavity, it is

$$Q > \frac{3}{4\pi^2} \left(\frac{1}{V} \right)$$

where V is the volume of the cavity expressed in cubic free-space wavelengths. This minimum Q is realized when the series reactance is eliminated through efficient feed and cavity design. For the simple capacitive slot-loaded cavity shown in Figure 8-6a, higher TE and TM modes will be generated with attendant high Q .

A broadband cavity-backed antenna can be realized by using a T-bar feed,¹⁷ as shown in Figure 8-7. A flat T-bar instead of the illustrated circular cross section will generate the same impedance if its width is equal to the diameter D .

The nominal input impedance to the T-bar is 125 Ω (approximate). To achieve the available bandwidth, a broadband impedance transformer is needed between the 50- Ω coaxial transmission line and the T-bar junction.

The dimensions for a broadband flat T-bar covering the frequency range 0.5 to 1.2 GHz are shown in the diagram of Figure 8-7. The VSWR does not exceed 3:1 in the frequency band and is less than 2:1 over 90 percent of the band.

The resonant frequency can be modified by use of dielectric or ferrite loading within the cavity.¹⁸ The reduction in cavity volume and aperture size results in increased Q , smaller bandwidth, and lower efficiency.

A shallow ridged-cavity crossed-slot antenna¹⁹ has been developed for wide-angle coverage in the ultrahigh-frequency range. The VSWR is dependent on the slot width, slot length, and cavity depth at the low end of the band. The ridge parameters tune the antenna in the midband and high-band frequencies. The VSWR is less than 2.7:1 from 240 to 279 MHz and under 2.1:1 from 290 to 400 MHz for cavity dimensions of 33 by 33 by 4 in.

An experimental square cavity-slot antenna (half scale) with crossed slots cut along the diagonal dimensions of the cavity is shown in Figure 8-8. The cavity configuration, ridges, and crossed-slot arrangement are illustrated. The slots are excited by four symmetrically located feed probes near the center of the cavity. Each opposite pair is connected to a wideband 180° hybrid. For circular polarization, the input ports of the two 180° hybrids are connected to a wideband 90° hybrid. The 3-dB beamwidth varies from 120° at the low end of the band to about 40° at the high end.

An earlier narrowband crossed-slot antenna was developed with a cavity depth of 2 in.²⁰ A stripline version of the cavity-backed slot antenna has been designed.²¹ This design was used for many years as a low-profile antenna for rocket payloads.

FIGURE 8-8 Cavity-slot configuration with circular polarization of a ridged-cavity crossed-slot antenna. Typical dimensions shown in inches (millimeters) for a frequency range of 480 to 800 MHz: a , 16.00 (406.4); d , 2.00 (50.8); b , 1.25 (31.75); W_1 , 2.50 (73.5); W_2 , 0.65 (16.51); h_1 , 1.50 (38.1); h_2 , 1.75 (44.45); L , 22 (558.8).

8.5 WAVEGUIDE-FED SLOT ANTENNAS

The waveguide opening onto a ground plane is commonly used in phased arrays and as a single element on curved as well as flat ground. An early analysis and experiment²² has been used extensively for checking various analytical methods. This early work has been extended to include a dielectric medium outside the slot,²³ as shown in Figure 8-9. Also given in Figure 8-9 are calculations and measurements that agree with those in Cohen et al.²² It is noted in Croswell et al.²³ that substantial energy is coupled into the dielectric slab in the form of surface waves. Another extension of this work includes dielectric plugs flush-mounted to the ground plane just inside the waveguide.²⁴ Dielectric plugs are very useful, but you must be careful of certain dielectric constants and plug thicknesses that can generate very significant higher-order aperture modes.

Similar analysis has been performed for circular waveguides.²⁵ The basic admittance of a typical TE₁₁-mode excited slot is given in Figure 8-10. This TE₁₁ excitation mode tends to couple less energy into the dielectric slab in the form of a surface wave. Hence the circular waveguide antenna was used in many early rocket reentry payload designs employing dielectric ablation materials.

The radiation characteristics of any annular slot (cut in an infinite ground screen) are identical with those of a complementary wire loop with electric and magnetic fields interchanged. In the case of the small slot, the radiation diagram is close to that of a small electric stub in the ground screen.

Consider a thin annular slot as shown in Figure 8-11. The polar axis of a spherical coordinate system being normal to the plane of the slot, the magnetic component of the radiated field is

$$H_{\phi} = \frac{aVe^{-jkr}}{120\pi\lambda r} \int_0^{2\pi} \cos(\phi - \phi') e^{jka \sin\theta \cos(\phi - \phi')} d\phi'$$

where a = radius of slot

V = voltage across slot

$K = 2\pi/\lambda$

For small values of a , that is, $a < \lambda/2\pi$,

$$H_{\phi} = j \frac{Ve^{-jkr}}{60r} \frac{A}{\lambda^2} \sin\theta \quad \text{A/m}$$

where $A = \pi a^2$ is the included area of the annular slot. The previous equation is valid for small slots of arbitrary shape.

FIGURE 8-11 Annular slot: (a) coordinate system and (b) vertical-plane pattern for a small-diameter slot

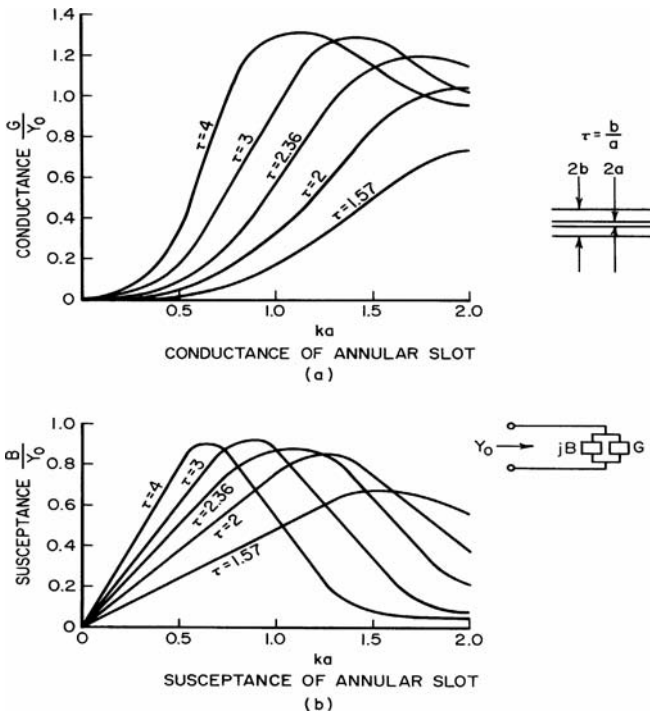

FIGURE 8-12 Admittance of a coaxial-fed annular slot in infinite ground plane

The integral in H_ϕ can be evaluated exactly as

$$H_\phi = j \frac{a V e^{-jkr}}{60r} J_1(ka \sin \theta)$$

where J_1 is the Bessel function of the first kind and the first order.

The radiation characteristics on a large but finite ground screen are closely approximated by the previous equations. There are slight perturbations because of edge effects that result in energy radiated into the shadow region plus modulation of the main radiation pattern.

The optimum excitation of an annular slot, i.e., least stored energy and lowest Q , results when the magnetic current distribution is uniform around the slot. One method for obtaining this result is to feed the annular slot by a coaxial transmission-line structure that has the same inner and outer diameters as the annular structure. Figure 8-12 consists of graphs of the conductance and susceptance in the plane of the aperture relative to the characteristic admittance of the feedline as a function of the radian length ka of the inner radius a . It is seen that the slot is at all times nonresonant and has a capacitive susceptance.

8.6 SLOT ANTENNAS ON FINITE AND CURVED GROUND PLANES

The annular slot is commonly used on aircraft as a UHF antenna because it produces a pattern similar to a short vertical dipole. Early research on annular slot antennas for the space

FIGURE 8-13 Roll-plane pattern of annular-slot antenna mounted on a model of the space shuttle (after Jones and Richmond²⁶ © IEEE 1974)

shuttle has been conducted and reported.²⁶ This analysis is an extension of the moment method to semi-infinite strips in an integral equation formulation. It was determined that for many cross sections through the body shape, the ϕ plane pattern was similar for either a two- or three-dimensional complex shape, as shown in Figure 8-13.

Additional extensive research has been performed for slot antennas on finite and curved ground planes. The early work done by Jones and Richmond²⁶ using integral equation solutions to determine the E -field distribution has been extended to apply to patches of surface instead of strips. This type of EM analysis, commonly referred to as the *method of moments (MOM)*, however, is limited to small surface volumes due to limitations in computers. An asymptotic method, the *geometrical theory of diffraction (GTD)*, has been developed that is not limited by the ground-plane size in wavelengths.

The GTD is an extension of *geometrical optics (GO)*, which is demonstrated in Figure 8-14. If you consider GO *only*, there are no fields in region III past the shadow boundary. Actually, the diffracted fields do exist and can be computed by GTD.²⁷

FIGURE 8-14 Two-dimensional electric conducting wedge and field regions (after Balanis²⁷ © Harper & Row 1982)

FIGURE 8-15 Aperture geometry in the principal-plane E -plane ($\phi = \pi/2$) (after Balanis²⁷ © Harper & Row 1982)

A simple example of the use of GTD is depicted in Figure 8-15. Following Balanis,²⁷ the total fields in all regions can be summarized as

$$E_t = E_{go}(r, \theta) + E_1^d(\theta) + E_2^d(\theta)$$

where

$$E_{go}(r, \theta) = E_0 \left[\frac{\sin\left(\frac{ka}{2} \sin \theta\right)}{\frac{ka}{2} \sin \theta} \right] \frac{e^{-jkr}}{r} \quad 0 \leq \theta \leq \frac{\pi}{2}$$

$$E_1^d(\theta) = \frac{E_0 \sin\left(\frac{ka}{2}\right)}{\frac{ka}{2}} V_B^{i,r}(d, \beta = \theta + \pi/2, 2) e^{jkd \sin \theta} \frac{e^{-jkr}}{r}$$

$$E_2^d(\theta) = \frac{E_0 \sin\left(\frac{ka}{2}\right)}{\frac{ka}{2}} V_B^{i,r}(d, \beta, 2) e^{jkd \sin \theta} \frac{e^{-jkr}}{r}$$

where

$$\beta = \begin{cases} \pi/2 - \theta & 0 \leq \theta \leq \pi/2 \\ 5\pi/2 - \theta & \pi/2 \leq \theta \leq \pi \end{cases}$$

and $V_B^{i,r}$ is the wedge diffraction coefficient. A typical result for a slot on a finite ground plane is given in Figure 8-16.

This work has been extended to slots opening to both square and elliptical cylinders,²⁸ as shown in Figure 8-17. Note that the patterns are qualitatively similar except for the ripple caused by diffractions at the edges of the rectangular cylinder. Further applications of GTD to three-dimensional surfaces for slot-antenna pattern calculations have been extensively pursued.

FIGURE 8-16 Principal *E*-plane amplitude patterns of an aperture antenna mounted on a finite-size ground plane (after Balanis²⁷ © Harper & Row 1982)

FIGURE 8-17 Radiation patterns of a thin elliptical cylinder and finite ground plane (TEM mode)

8.7 SLOT ANTENNAS ON CYLINDERS, CONES, AND SPHERES

A common design problem for spacecraft, aircraft, and rocket antennas is to determine the pattern and impedance of such antennas when located on curved dielectric-coated surfaces where the conformal dielectric is a radome, a reentry ablator, and/or an absorber. To obtain first-order results, it has been found useful to consider the radiation characteristics of slot antennas on cylinders, cones, and spheres.

The best early summary for slots on cylinders is a book by Wait.²⁹ Accurate calculations of the patterns of a slot on an uncoated cylinder have been published by Knop and Battista,³⁰ a few of which are given in Figure 8-18; note that $c = ka$. If a coating is applied to the cylinder surface, a series of azimuthal surface waves can be excited that can produce major ripples in the pattern depending on dielectric constant and thickness. An estimate of such modes can be made using equations in Croswell et al.²³ Measured patterns of a coated azimuthal slot on a cylinder are available.³¹ Similar effects were noted for axial slots on dielectric-coated cylinders (unpublished notes).

The admittance of a slot on a coated cylinder also has been computed.³² The admittance is about the same as that on a flat coated ground plane with

$$ka = \frac{2\pi a}{\lambda} \geq 3 \text{ to } 4$$

FIGURE 8-18 Equatorial-plane power patterns for a half-wavelength slot on an uncoated cylinder (after Knop and Battista³⁰ © IEEE 1961)

Interestingly, about $2ka$ terms are required to compute a convergent value of conductance. However, the susceptance requires about 75 to 100 terms regardless of ka . The susceptance in this formulation represents the near field of the slot.

A major problem on early satellites was to design an antenna having a quasi-isotropic radiation pattern on spherical-shaped surfaces with large values of ka . Early data were available for small spheres, but patterns for larger spheres excited by a parallel-plate waveguide were first considered by Bugnolo,³³ who took great care to make precise measurements. More practical forms of the large spherical antenna excited by a slotted waveguide and a modified parallel-plate waveguide have been repeated.^{31,34}

Another slot antenna of great interest for missiles and aircraft is the slotted cone. This problem is dominated by the tip diffraction.³⁵ Additional results for a slot on a cylinder fed by a cavity are given in Swift et al.³⁶ Antennas similar to this were mounted on sphere-tipped cones and used for telemetry antennas on reentry payloads.

9.1 INTRODUCTION

Geometric simplicity, efficiency, polarization purity, conformal installation, and ability to radiate broadside beams and vertically polarized E -plane beams at very near grazing angle above a ground plane make slot-antenna arrays ideal solutions for many radar, communications, and navigation applications. Especially today with the desire to make antennas for aircraft as low profile as possible to reduce drag and conserve fuel, slot antenna arrays can be positioned above wings and on top of the fuselage while having the capability to look toward the horizon. Classical slot arrays are depicted as narrow nonconductive slits etched or milled into the host metallic ground plane. They are characterized by the methods used to feed or excite the slots. Without what is behind the slot opening being seen, slot radiators appear similar on the surface of the ground plane. Narrow conformal slots tend to be narrowband (< 5 percent f_0) and have high cross-polarization isolation when operating near their resonant frequency. Wider slots can exceed an octave bandwidth given a well-matched feed. However, polarization purity is usually not as good as with the narrower slots. Conformal slot arrays are generally limited in bandwidth because the array lattice spacing has to be large enough to accommodate the waveguide and feed structures behind the slots without creating grating lobes.

Conformal slot elements can be fed in a variety of ways: (1) tapping into a transmission line such as a waveguide, (2) coupling to a resonant cavity, and (3) feeding them directly with voltage sources across the slots. Each method has some impact on the radiation performance and operating bandwidth of the slot radiators and hence the array. This chapter focuses on the first approach, which is the transmission-line method whereby slots are cut along a waveguide to couple energy in a controlled manner to slots that radiate. Waveguide-fed array systems are either traveling-wave or standing-wave approaches. Because waveguides are dispersive transmission lines, the array excitation along the waveguide has a differential phase relationship between elements that changes with frequency, causing the array beam to scan. For fixed beam (nonscanning) arrays, the waveguide is converted into a resonant, standing-wave structure. Before the advent of broadband MMIC T/R module technology, waveguide-fed slot arrays were most common in microwave radar applications. Today corporate feed networks offer a greater flexibility to excite slot arrays over a broader bandwidth. They are most effective when T/R modules, comprised of amplifiers, attenuators, and phase shifters or time delay devices, are connected in series with each array element. The slot elements can be phased independently to scan a beam anywhere in a hemisphere above their host ground plane. However, such large phased arrays that have independent control of every radiator are still prohibitively expensive. Therefore array architectures are employed that utilize hybrid scan approaches where electronic scanning is used in one plane, and either mechanical or frequency scanning is used in the other plane. Thus waveguide slot arrays can still provide a very cost-effective solution to fulfilling many high performance array needs.

9.2 WAVEGUIDE SLOT RADIATORS

The radiating elements of a waveguide slot array are an integral part of the feed system, which is the waveguide itself. This simplifies the design since baluns or matching networks are not required. A familiarization with the modal fields within a waveguide is necessary to understand where to place slots so that they are properly excited. Narrow slots that are parallel to waveguide wall currents do not radiate. However, when a slot is cut into a waveguide wall and it interrupts the flow of current, forcing it to go around the slot, power is coupled from the waveguide modal field through the opening to free space. To have good control of the excitation of a linear slot array, it is recommended that the waveguide

FIGURE 9-1 Slots cut in the walls of a rectangular waveguide. Slot *g* does not radiate because the slot is lined up with the direction of the sidewall current. Slot *h* does not radiate because the transverse current is zero there. Slots *a*, *b*, *c*, *i*, and *j* are shunt slots because they interrupt the transverse currents (J_x , J_y) and can be represented by two-terminal shunt admittances. Slots *e*, *k*, and *d* interrupt J_z and are represented by series impedance. Slot *d* interrupts J_x , but the excitation polarity is opposite on either side of the waveguide centerline, thus preventing radiation from that current component. Both J_x and J_z excite slot *f*. A Pi - or T -impedance network can represent it.

only operate in a single mode, preferably the lowest mode. When a waveguide as shown in Figure 9-1 is excited with a TE_{10} mode and the ends are terminated in a matched impedance, the fields are given by Eq. 9-1.

$$\begin{aligned} H_x &= \frac{-\beta_z}{\omega\mu} E_o \sin(\beta_x x) e^{-j\beta_z z} \\ E_y &= E_o \sin(\beta_x x) e^{-j\beta_z z} \\ H_z &= \frac{j\beta_x}{\omega\mu} E_o \cos(\beta_x x) e^{-j\beta_z z} \end{aligned} \quad (9-1)$$

where

$$\begin{aligned} \beta_x &= \pi/a \\ \beta_z &= \sqrt{k^2 - \beta_x^2} = \frac{2\pi}{\lambda_g} \\ k &= \frac{2\pi}{\lambda} = \frac{\omega}{c} \\ \lambda_g &= \frac{\lambda}{\sqrt{\lambda_c^2 - \lambda^2}} \\ \lambda_c &= 2a \end{aligned} \quad (9-2)$$

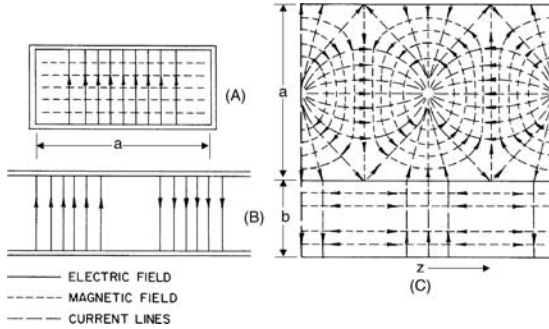

FIGURE 9-2 Surface-current distribution for rectangular waveguide propagating TE_{10} mode: (a) Cross-sectional view shows E - and H -fields. (b) Longitudinal view shows polarity of E -field along waveguide. (c) Surface views show top and sidewall currents and H -field.

The currents J along the inner waveguide wall surfaces are proportional to H .

$$\vec{J} = \hat{n} \times \vec{H} \quad (9-3)$$

The currents along the top and side walls are shown in Figure 9-2. At the top inner wall surface ($y = b$),

$$\begin{aligned} J_x &= -j \frac{\beta_x}{\omega \mu} E_o \cos(\beta_x x) e^{-j\beta_z z} \\ J_z &= -\frac{\beta_z}{\omega \mu} E_o \sin(\beta_x x) e^{-j\beta_z z} \end{aligned} \quad (9-4)$$

On the bottom inner wall surface ($y = 0$),

$$\vec{J}_{\text{bottom}} = -\vec{J}_{\text{top}} \quad (9-5)$$

On the inner sidewalls ($x = 0$, $x = a$), there is only a \hat{y} -directed current with the same phase.

$$J_y = -j \frac{\beta_x}{\omega \mu} E_o e^{-j\beta_z z} \quad (9-6)$$

Rotating the slot with respect to a peak current direction can control the power coupled to a slot. For example, slot e couples maximum power, while the power is proportional to $\sin^2 \phi$ for slots d and c . Another way to control coupled power is to take advantage of the natural field intensities within the waveguide by locating the slots accordingly. For example, J_x is a null at the center of the surface wall and varies sinusoidally as you approach the edge. Therefore, by offsetting longitudinal slots such as slot a from the center of the waveguide, the power coupled to the slots can be adjusted. The ability to control the excitation of slots in a linear waveguide is important in order to design arrays with tapered sidelobes. Moreover, depending on how the array is fed, the coupling of the waveguide to the slots must vary progressively down the length of the waveguide if the first elements are not to radiate all the power, with little power left for the remaining elements.

Slots are classified by their shapes, locations in the rectangular waveguide, and how they are arrayed. Slots are usually about $\lambda/2$ long at the center frequency of their operating bandwidths. For slots located on the wider waveguide surfaces ($a = \lambda_c/2$), there is plenty of room for offset and rotated slots. For slots cut into the side walls, where the rotation angle ϕ cannot be large and $b < a/2$, there is usually not enough room for $\lambda/2$ slots. The slots are either extended or “wrapped around” into the adjoining surfaces (e.g., slot *b* in Figure 9-1) or the slots are end loaded (e.g., *C* and *I* slots) to resonate them. Wrapped-around slots are not as desirable in conformal planar array configurations because the elements have to be slightly elevated above the ground plane or gaps or spacers provided between waveguides. Complicated slot designs are also more costly to manufacture.

Slots are usually represented as rectangular shapes, which simplifies analysis. Unless they are etched on a metallized substrate, narrow slots on the broad wall of a waveguide are usually fabricated by a milling process in which rounded ends are a natural output of the process. Wider slots can be manufactured with straight ends but with rounded corners. The impact of rounded ends is small but does change the impedance of the slot and hence its resonant frequency.

9.3 SLOTTED WAVEGUIDE ARRAY DESIGNS

A slotted waveguide array is, by its very nature, a linear or *stick* array. Planar slotted waveguide arrays are comprised of multiple stick arrays placed side by side, as shown in Figure 9-3. The mutual coupling between slots in a planar array is high, especially between slots along the *E*-plane, such that dimensional and positional modifications to the slots are needed to compensate for resonant frequency changes. Most slot array designs are for fixed beam or mechanically scanned applications where the array is mounted on a gimbaled pedestal to steer the beam. Low loss beamforming networks to feed the arrays can also be constructed out of waveguides. Sum/difference waveguide components, such as magic-*T*s,

FIGURE 9-3 Planar longitudinal shunt-slot array. Adjacent waveguides are indicated at right.

simplify the implementation of monopulse networks in planar arrays for use in radar or satellite tracking applications. Electronic scanning is possible along the axis transverse to the waveguide stick subarrays. Phase shifters and attenuators are included in the network that feeds signals to each stick subarray. However, the active impedance of the array is highly affected with scan angle, especially in the case of longitudinal slots where the polarization is such that the E -plane is the scan plane. Hence the array design must be optimized with scanning requirements in mind.

If a TEM transmission line fed slot elements, the beam would radiate at a fixed angle as a function of the delay between elements, independent of changes in frequency. Waveguides are dispersive and the group velocity or delay between slots varies with frequency. Therefore the beam radiated by a slot array scans along the longitudinal axis of the waveguide as the frequency changes. The group delay is not a linear function of frequency, and it increases rapidly as the frequency decreases to near cutoff frequency. For a fixed beam array, this is a feature, or a problem as the case might be, that limits the bandwidth over which the array can be used. Frequency scanned radars make use of this feature to scan a pencil beam in a plane by “chirping” the signal. The array is either mechanically scanned in the other plane or electronically scanned through a network with phase shifters.

Waveguide slot arrays are classified into two groups: (1) standing-wave arrays and (2) traveling-wave arrays. The standing-wave arrays have elements spaced $\lambda_g/2$ and radiate a beam broadside to the waveguide. The fields repeat in a waveguide every $\lambda_g/2$ but are of opposite phase. Therefore the slots are placed in a $+/-$ configuration so that they are all fed in phase. Because of dispersion in a waveguide, the bandwidth around the center operating frequency cannot deviate by more than a few percent without causing rapid deterioration of the beam pattern and sidelobe levels, especially for the standing-wave array. Standing-wave arrays can be fed either at one end of the waveguide with the other end terminated in a matched load or short circuit, or at the center of the waveguide with matched load or short circuit terminations at the waveguide ends. Short circuit terminations provide for a more efficient array since the reflected wave from the waveguide ends can be phased with the incident wave. This allows for a higher power handling capability. If a slightly larger bandwidth is desired, matched terminations minimize reflected waves that potentially could cause the array to radiate another beam in the opposite direction.

Traveling-wave arrays are used in applications where the direction of the main beam is pointed at angles that are not broadside to the waveguide wall or where frequency scanning is desired. Inter-element spacing does not have to be the same between the elements, and $\lambda_g/2$ spacing is particularly avoided. In designing these arrays it is important to have wide-band terminations with a very low VSWR to prevent the formation of reflected or backward waves. Backward waves appear to originate from the opposite end of the waveguide and excite the slots to produce unwanted beams in the backward direction. Traveling-wave arrays can only be fed from the ends of the waveguide. To maximize the impedance bandwidth of the array, the slot elements are designed to be resonant at their center operating frequency, hence they are called *resonant* slots. This should not be confused with resonant arrays discussed earlier which, unlike traveling-wave arrays, have a standing-wave condition within the waveguide.

Initial Slot Array Design Considerations

One advantage of waveguide slot arrays is that not only the radiating aperture but also the feed network can be made from waveguides. Waveguides can couple energy to other waveguides in a very precise manner. They are also the preferred low loss transport medium to feed arrays at X-band frequencies and above. Several methods can be used to manufacture the radiating aperture. One popular way is to mill waveguide troughs into a solid piece of aluminum and

then to machine the slots. Therefore waveguide width can be made to any custom dimension that is not in cutoff at the operating frequency. This allows design flexibility in the selection of standard waveguide sections for the feed network in the rear of the array aperture. However, be careful to keep inter-element spacing less than a free-space wavelength λ_0 to prevent the appearance of grating lobes. For scanning arrays, the spacing between elements should be closer to $\lambda_0/2$ in the plane of scan. For resonant slotted-waveguide arrays, the element spacing along the waveguide must be equal to half the waveguide wavelength ($\lambda_g/2$) since all the element excitations must be in-phase. For nonresonant slotted-waveguide arrays, inter-element spacing is slightly larger or smaller than $\lambda_g/2$. The waveguide wavelength is larger than the free-space wavelength for the same frequency.

Designing slot arrays is similar to designing any other fixed beam or phased arrays. Once the array requirements are determined, such as gain, sidelobe level, beamwidth, bandwidth, polarization, input VSWR, scan impedance, cross-polarization level, power-handling capability, etc., then the array element excitations are calculated. Most array design codes available that consider mutual coupling between array elements utilize the infinite array approach, which is numerically efficient. However, it does not include array edge and truncation effects. These must be computed by low-frequency methods such as MOM or FEM. Because slots will have different excitations although they have the same resonant frequency, they will have different offset positions from the centerline of the waveguide to achieve their resonant conductances and/or resistances, as in the case of longitudinal shunt slots. Series and edge-wall slots are rotated along the waveguide axis. The element layout is not exactly periodic. Hence slot placement and orientation must be approximated. Once an array excitation is obtained that includes compensation for edge and radome effects, then the element coupling can be readjusted. Since the elements have been moved, a last performance prediction is made to verify that performance will be as desired. This design process is outlined in Figure 9-4.

To optimize bandwidth performance, the slots are designed to be resonant at midband for either resonant or nonresonant arrays. The power coupled from the waveguide and

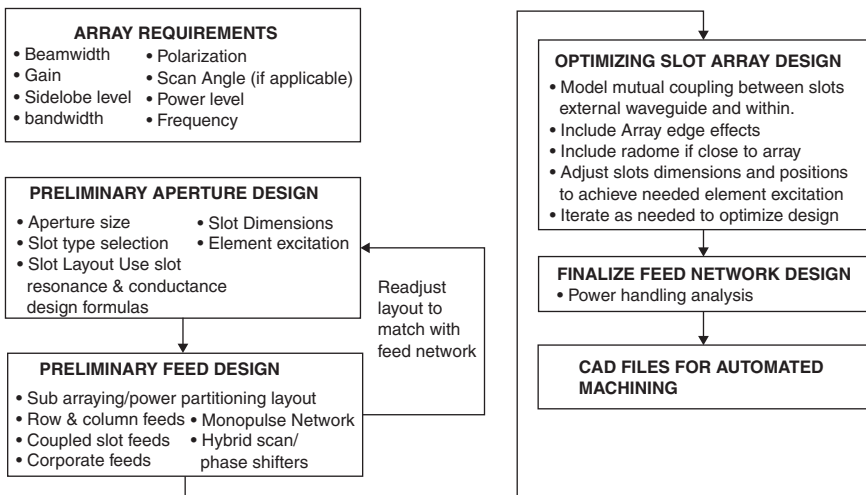

FIGURE 9-4 Slot array design process. Once the slot element excitations are determined to meet the array beamwidth, gain, and sidelobe requirements, the next step is to lay out the slots onto waveguide. Considerations must be given to the beamformer design. One or more design iterations will be needed to optimize the design.

radiated by the slot is proportional to slot conductance or resistance. If P_i is the fraction of the total waveguide power radiated by slot i , the normalized shunt-slot conductance or series-slot resistance is given by

$$g = 2P/V^2 \quad r = 2P/I^2 \quad (9-7)$$

where V or I are respectively the voltage or current across the slot. The transmission-line or scattering-matrix theories can be used to determine V and I and, therefore, g and r . Methods to achieve certain slot characteristics are described in later sections. First let us examine the differences between the various types of slot arrays.

Resonant Slotted-Waveguide Array Design

Linear and planar resonant slotted-waveguide arrays are used in many applications, especially radar. The advantage of using a planar slotted waveguide array over a parabolic reflector, for example, is that the array is thinner, the beam and sidelobes can be shaped, and two-axis monopulse is more easily implemented. The operating principle of resonant slotted-waveguide arrays is that the slot elements are excited by a standing wave set up within the waveguide, and hence all have the same phase. The impedance (admittance) repeats itself in a transmission line at every $\lambda_g/2$. If the impedances (admittances) of series (shunt) slots are real at the center resonant frequency, then the impedances (admittances) of the previous slots in the waveguide just add together at the next slot. The objective is to have the total impedance (admittance) contribution of all the slots at the feedpoint be equal to the intrinsic impedance (admittance) of the waveguide. This guarantees the lowest VSWR at the center operating frequency. The slots are located along the waveguide where their current excitation is nearly maximum. Transverse currents that are in phase with the E -field excite longitudinal and side-wall slots. Therefore they are centered along the waveguide at voltage maxima. Longitudinal currents that are out of phase with the E -field excite series slots. Therefore they are centered at voltage minima along the waveguide.

Linear Resonant Slot Arrays The design of a linear waveguide slot array begins by first determining the aperture distribution, and hence the slot excitation, required to achieve the beamwidth, gain, and sidelobe level needed at the center frequency of the operating frequency band. Since the slot elements are $\lambda_g/2$ apart and in phase, the array pattern along the longitudinal plane of the waveguide is controlled by number of elements and their excitation amplitudes. Depending on the type of slots used, their amplitudes are controlled by offsetting the elements from the centerline of the waveguide, by rotating the slots at their centers, or by a combination of both offset and rotation. The square of the voltage excitation of a slot is proportional to its radiated power and its resonant conductance. For a linear array of N slot elements we have

$$\sum_{n=1}^N g_n = W \quad (9-8)$$

$$g_n = \frac{A^2(n)}{\sum_{i=1}^N A^2(i)} = KA^2(n) \quad n = 1, 2, \dots, N \quad (9-9)$$

where g_n is the resonant conductance of the n th slot normalized to the waveguide admittance Y_0 , $A(n)$ is the given aperture voltage distribution at the n th-slot location, K is the power normalization factor, and W equals 1 for end-fed arrays or 2 for center-fed arrays.

When a waveguide is fed at the center, the normalized conductances looking into both ends are in parallel at the feedpoint, which is why W is 2. Equations 9-8 and 9-9 are then solved for g_n , and the design is completed by dimensioning the slots and positioning them at the locations where they will resonate at the correct frequency with conductance g_n . Figure 9-5 shows the two preferred methods for feeding resonant arrays. For both end-fed and centered approaches, the distance between the short-circuit waveguide termination and the first end slot is $\lambda_g/4$. The short circuit reflects as an open circuit, which has an admittance of zero, to the first slot from the end. This is in parallel with the conductance of the end slot.

Linear slotted arrays utilize either longitudinal shunt slots or edge-wall shunt slots as radiating elements. Narrow longitudinal shunt slots radiate array patterns that have very high cross-polarization isolation. An example of an end-fed, dual-sided longitudinal linear slot array is an X-band array, as shown in Figure 9-6. For this array, slots have been placed on both wide walls of the waveguide. The array radiates an omni-azimuthal, horizontally polarized pattern. For a vertically polarized pattern, the array would have to be comprised of edge-wall shunt slots, which are also excited by a single transverse current. However, the cross-polarization isolation with edge slots is not as good as with the longitudinal slots because every other element is canted in a different direction, and the polarization purity is dependent on the uniform excitation of the slots and external cancellation of the cross-polarized field components. Rotated series slots also have a lower cross-polarization isolation level as compared with the longitudinal shunt slots and edge slots due to the rotation of the slots and due to some excitation of the slots by the transverse currents.

The number of slots that can be arrayed in a single waveguide section is limited. The impedance bandwidth of the waveguide array narrows rapidly with an increasing number

FIGURE 9-5 Linear resonant waveguide slot arrays with longitudinal slot elements. In (a) the array is fed from the waveguide end. In (b) the array is fed from the center through an E -plane T coupler. Figure 9-5b could also be fed by a series or shunt slot from another waveguide on the backside.

FIGURE 9-6 End-fed resonant longitudinal slot array. Slot elements are located on both sides of the waveguide to provide an almost omni-azimuthally, horizontally polarized radiation pattern at 10 GHz. The slots on either side are directly behind each other. The background can be seen through the slots. A dip of 10 dB in the radiation pattern occurs at 90°. The return loss at 10 GHz is -13 dB. of elements.¹ Any small deviation in admittance from a perfectly resonant element as was designed is rapidly transferred to other elements, causing the reactive admittance component to grow rapidly. Therefore any mismatch rapidly builds up at the feedpoint as the frequency changes. A common subarray size varies from 12 to 16 elements for an impedance bandwidth of 4 percent to 3 percent, respectively.

Planar Resonant Longitudinal Shunt and Series Slot Arrays Resonant planar arrays are used in many radar applications and preferred over reflector antennas because the beam pattern can be shaped and monopulse sum and difference ports for tracking can be implemented directly. Many present-day radars still utilize fixed beam apertures that are mechanically scanned. Others are hybrid scanned, electronically in one plane and mechanically in the other. Planar arrays are constructed by placing several linear arrays side by side, as shown in Figure 9-7. A large planar array may consist of several subarrays, and each subarray may consist of several linear arrays. Because the minimum width of a waveguide is equal to the half wavelength of its cutoff frequency, inter-element spacing between adjacent waveguides at the operating frequency is greater than $\lambda/2$, which can create grating lobes beyond certain scan angles in the plane orthogonal to the waveguides. As with standard phased array design, the radiation pattern of the array is a function of the external placement and excitation of the elements relative to each other. Therefore wall thicknesses between adjacent waveguide sections are made as thin as structurally acceptable. When the waveguide width is still too large for grating lobe-free beam scan, you can design the structure using custom waveguide of lesser width or turn the waveguide on its side and utilize edge-slot elements.

Large resonant planar arrays are usually fed using corporate or series-fed waveguide networks like the one seen on the backside of the planar array in Figure 9-8. The number of waveguide subarrays that can be fed by a secondary waveguide coupled by series or shunt slots is limited by impedance bandwidth to the same number of slot elements that can be excited in a single linear waveguide array. Coupling is done by slots rotated to an angle that

FIGURE 9-7 Resonant longitudinal shunt-slot array fed by phase shifter network located at the ends of the waveguides. This figure shows one subarray “stick” per row. Each row could have multiple sticks. This array will scan a beam in the *E*-plane, the direction orthogonal to the waveguides.

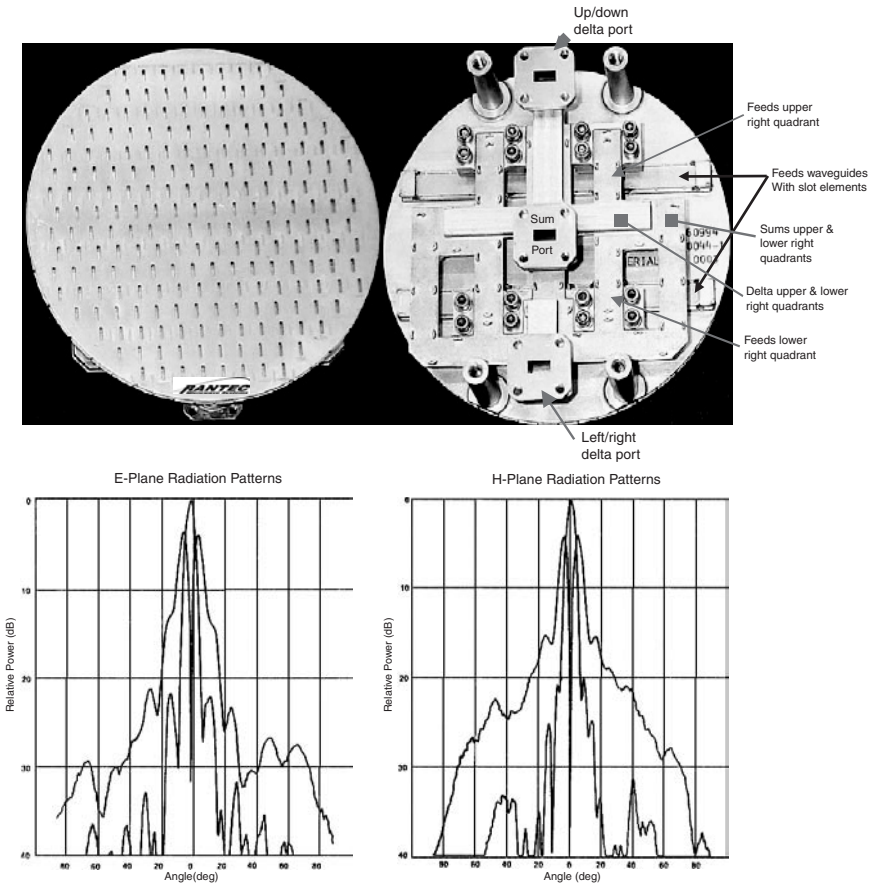

FIGURE 9-8 Ka-band resonant longitudinal shunt slot fixed beam array. The beamformer has been designed to provide up/down and left/right monopulse capability. *E*-plane and *H*-plane sum and difference patterns indicate sidelobes lower than -20 dB and a difference null depth of -32 dB.

couples the correct amount of power into each subarray. Depending on how many subarrays must be fed, several layers of waveguide might be required in the network to feed the array. In general, the series-slot center-feed system is a simpler and more compact design than the waveguide end-feed system for the same antenna size. Caution should be exercised, however, since the feed slots sometimes couple strongly to the radiating slots above them. This is especially true for series slots and edge slots. Longitudinal shunt slots do not couple strongly unless the waveguide height has been greatly reduced. For those arrays that have phase shifters, the row or column divider manifolds are brought to a common edge or plane where the phase shifter network is attached.

Series resonant slot arrays are designed in a similar fashion as longitudinal shunt-slot arrays. Because their cross-polarization isolation is not as good as the longitudinal slots, they are not often used as a primary radiator. Their use is more often as the feed distribution array behind the radiating array. The reason for their preference in this application is that the elements can remain centered about the same waveguide centerline and be able to feed other waveguides within $\lambda/2$ inter-waveguide spacing. The slot elements are positioned along the centerline of the waveguide, rotated at an angle from the centerline to couple energy from the waveguide to the slot. (The rotation angle is sometimes called the *inclination* angle.) Unlike the shunt slot, whose resonant length is affected by its offset from the centerline, the resonant length of the series slot is rather insensitive to the rotation angle. When series slot elements are placed within $\lambda_g/2$ along the waveguide, they are excited with opposite polarity. This polarity change is reversed by rotating the slot to the negative angle from the centerline. When the field radiated by each slot is separated into a component polarized along the direction of the waveguide and one orthogonal to the waveguide, the longitudinal components cancel each other and the transverse components combine. This is why the *E*-plane of the series slot array is also perpendicular to the axis of the waveguide. The cross-polarization problem is exacerbated when the array is fed with a tapered excitation whereby the next element has a different amplitude than the previous. In this case the external cross-polarization component of each element does not cancel itself fully, thus leaving a residual cross-polarized component.

Once the required slot excitations for either the longitudinal shunt slots or the series slots have been determined, the slot conductance or resistance is then calculated before determining the slot dimensions and offset from the center waveguide line for the shunt elements or the rotation angle for the series slots. By using the slot equivalent circuit and assuming that all the slots are at resonance, the normalized slot conductances $g_{m,n} = G_{\text{slot}}/Y_{o \text{ waveguide}}$ or series resistances $r_{m,n} = R_{\text{slot}}/Z_{o \text{ waveguide}}$ in the waveguides are determined by

$$\begin{aligned} \sum_{n=1}^{N_k} g_{m,n} &= W \\ \sum_{n=1}^{N_k} r_{m,n} &= W \end{aligned} \quad (9-10)$$

where N_k is the number of elements in a given waveguide section in row m and $W = 1$ for end feed or $W = 2$ for center feed. Let the power radiated by the slots of a waveguide subarray section be

$$B_k^2(m) = \sum_{n=1}^{N_k} A^2(m,n) \quad m = 1, 2, \dots, M \text{ and } k = 1, 2, \dots, K \quad (9-11)$$

where K is the number of waveguide sections in a given array row m . Therefore, $g_{m,n}$ and $r_{m,n}$ are given by

$$\begin{aligned} g_{m,n} &= \frac{A^2(m,n)}{B_k^2(m)} \\ r_{m,n} &= \frac{A^2(m,n)}{B_k^2(m)} \end{aligned} \quad (9-12)$$

Once g and r are known, then the design tables can be used to arrive at initial slot dimensions and positioning before attempting an optimization. Commercial software is available to assist in the design of slot arrays. It is still a numerically challenging problem to compute all mutual coupling and edge effects of moderately large arrays. Therefore, available software probably still has to make approximations to arrive at a design. When a truly high performance array is desired, such as one with very low level sidelobes or very sharp monopulse nulls, designers might have to write their own custom code to optimize the design.

Resonant Edge-Wall Shunt-Slot Array

The edge slot is cut into the narrow wall of a waveguide. The slot is designed to operate at resonance, and its length is nearly half a wavelength. Because the edge dimension of a waveguide is usually less than half its width, the depth of the slot cut runs into the broad wall. The slot length is approximately equal to its visible length on the edge wall added with twice the length of the cut depth into the broad wall, which accounts for the cuts into the upper and lower broad walls. Planar arrays of these elements are not practical because spacers between adjacent waveguides need to be placed to prevent the slots edges from being covered up. This is not the case when the whole slot can fit on the narrow edge-wall. Thus planar slot-antenna arrays often use end-loaded slots such as C or I slots as seen in Figure 9-9 to allow the slots to resonate on the edge-wall surface. There usually is no advantage in using edge-wall shunt

FIGURE 9-9 Resonant edge-wall, shunt-slot array. The slot tips are enlarged to resonate the slots at a shorter length. Note that when an edge array is fed from the center with an H -plane T or edge-wall coupler, the polarization of the elements is reversed on half of the array. (Photo courtesy of Microwave Systems, Inc.)

slots in a planar array unless closer inter-element spacing is needed to electronically scan a beam orthogonal to the waveguide axes with minimal grating lobes.

Edge-slot arrays also have difficulty achieving high cross-polarization isolation. Because the array is comprised of elements with opposing tilt angle, the cross-polarization isolation is achieved in spatial combining. If the slot amplitudes are not all of the same level, then the cross-polarization components do not fully cancel.

Edge-wall slotted waveguides are usually fed from the end because center feeds tend to couple strongly to slots on the opposite edge. The transverse currents in the waveguide flow around the walls in what could be described as a “square” perimeter orthogonal to the waveguide axis. When a slot interrupts the current flow along a wall, the currents along that whole perimeter are affected. Therefore, other shunt slots on that perimeter will couple to that current. Despite the preference for end-fed waveguides, it is often necessary in larger arrays to feed the edge-slotted waveguides from the opposite edge-wall at the center. Coupling to an edge waveguide wall is known as an *H*-plane coupler. The signals coupled to the center of the host waveguide are initially in phase before they propagate to the opposite ends of that waveguide. Therefore it is necessary to reverse the phase of the slot elements on one end of that waveguide if it is going to form a broadside beam.

Determining the excitation for the elements of the edge wall, shunt-slot elements follows the same computational EM modeling process as with the series and longitudinal slots. Once the excitations $A(m, n)$ are known, then the normalized slot conductance is computed as per Eqs. 9-10 to 9-12. The slot voltage is proportional to $V_0 \sin(\theta)$ where θ is the tilt angle from the vertical. Therefore the conductance and coupled power will be proportional to the square of the voltage. A slot design that meets the required conductance is difficult to obtain. Until recently, when results of MOM and FEM modeling of edge slots were published,^{2,3} there was no simple formulation for edge slots that cut into the broad walls. Slot characteristics were obtained through scattering parameter measurements only.

Traveling-Wave Slot-Array Design

Unlike resonant waveguide slot arrays, traveling-wave slot arrays avoid resonances or standing-wave conditions in the waveguide. Hence the slots of traveling-wave arrays are spaced by either more or less than one-half waveguide wavelength. As in the case of resonant waveguide slot arrays, resonant slots are used in traveling-wave arrays to maximize frequency-bandwidth performance. A matched load terminates the slotted waveguide to prevent the formation of a secondary beam due to reflected waves. Although much effort is put into minimizing reflections that occur from the termination and also from every slot along the waveguide, sometimes it is necessary to create controlled reflections to cancel the appearance of secondary lobes that are not due to grating lobes.

Inter-element slot spacing is selected to be close to one-half waveguide wavelength ($\lambda_g/2$). Therefore the polarity of adjacent slots is of the opposite sense. For example, adjacent longitudinal shunt slots are on opposite sides of the guide centerline, and adjacent edge-wall shunt slots are inclined to opposite sides of the vertical centerline. The alternating displacement or rotation with respect to the waveguide axis of successive slots may produce grating lobes.^{4,5} If the main beam of the traveling-wave slotted array is pointing far away from broadside, the upcoming grating lobe level may exceed the desired sidelobe level. The grating lobes can be pushed out of the visible array space by choosing a suitable inter-element spacing. The restrictions on grating lobes can be relaxed when the slot element pattern amplitude is taken into consideration at the angles where the grating lobes are appearing.

There are two types of traveling-wave slot-antenna arrays: (1) the uniformly spaced element array that produces a low-sidelobe pencil beam and (2) the nonuniformly spaced element

array that is used in shaped-beam array designs. Longitudinal shunt slots, edge-wall shunt slots, and rotational series slots are used in both traveling-wave type arrays. Traveling-wave arrays are always fed from the end of the waveguide. The progressive phase shift between elements, which changes with frequency, causes the beam to scan. This means that as power is fed into the waveguide, the first slot couples some power, leaving the remaining power to travel to the next slot, and so on. By the time the remaining power arrives at the last slot, that slot must couple most of it to meet its prescribed excitation level. Since there are too many factors that can affect the precise amount of power that travels from slot to slot, and since it is impossible for the last slot to couple 100 percent of the remaining power, the array is designed to let about 5 percent to 10 percent of the power be absorbed by the termination. This helps to stabilize the excitation of the last few slots before the termination.

The process to determine the slot conductance or resistance can be simplified as follows if the waveguide can be considered as lossless and if the reflection coefficient due to each slot is minimal. Consider the equation for the power input to the waveguide

$$P_{in} = P_{\text{all slots}} + P_{\text{load}} = K \sum_{i=1}^N p_i + P_L \quad (9-13)$$

where

P_{in} is the input power to the waveguide

$P_{\text{all slots}}$ is the power radiated by all the slots in that waveguide

$P_{\text{load}} = P_L$ is the power absorbed by the load at the end of the waveguide

p_i is the normalized power radiated by slot i given by $A^2(m,i)$, the calculated slot excitation

K is the power calibration factor given by

$$K = \frac{P_{in} - P_L}{\sum_{i=1}^N p_i} \quad (9-14)$$

If slot 1 is the slot closest to the feed end of the waveguide, then the first shunt slot conductance (resistance for series slots) is given by

$$g_1 = \frac{Kp_1}{P_{in}} \quad (9-15)$$

The conductance at the second slot is found by subtracting the power absorbed by the first slot.

$$g_2 = \frac{Kp_2}{P_{in} - Kp_1} \quad (9-16)$$

The conductance for the third slot would include the power from the second slot in addition to the power from the first slot. This process is iterative until the last slot N . The conductance for that slot is given by

$$g_N = \frac{Kp_N}{P_{in} - K \sum_{j=1}^{N-1} p_j} \quad (9-17)$$

Note that this approximate design is valid only if the largest slot resonant conductance g_{\max} satisfies the following relationship:

$$|g_{\max} \csc k_g d| < 0.447 \quad (9-18)$$

where d is the spacing between elements and $k_g = 2\pi/\lambda_g$. Through the proper choice of P_L the resultant slot conductances can usually be made to satisfy this criterion, although undesirably high power may be dissipated at the termination.

For arrays with many slots per waveguide section, the determination of the slot conductance by Eq. 9-17 is very accurate since the coupling factor has to be low. However, with fewer elements the coupling factor is higher, and the slots create VSWR mismatches. For this case, K_p determines the power that must be absorbed per element. A transmission-line circuit is drawn representing the waveguide. The slots are shown as lumped loads at their proper locations along the transmission line. In this case, the analysis begins at the end of the transmission line working up toward the feed. The assumption can be made that the load is perfectly matched unless its VSWR is known. That admittance is translated to the position of slot N . To do this, the reflection coefficient must first be determined. The lump admittance of the slot, which is not yet known, is now in parallel with the translated transmission-line admittance. Based on earlier knowledge of the power going to the load and the power going to slot N , the slot admittance can be calculated from the ratio of slot admittance to the total admittance at that point, which is the sum of the slot admittance and the translated admittance from the load. The solution should not be much different from what was calculated in Eq. 9-17. However, an effort should be made to choose a slot admittance that minimizes the reflection coefficient from the combined admittance of slot and the translated line admittance. The total admittance at slot N is now translated to slot $N - 1$ and the process is repeated. In some cases the slot admittance might need extra susceptance to minimize the reflections. There is little that can be done in slot offset and rotation to get a reactive component, but posts or other compensators within the waveguide in the vicinity of the slot might be needed.

Uniformly Spaced Traveling-Wave Slot-Array Design A uniformly spaced traveling-wave slot array can be designed to produce a low-sidelobe pencil beam with larger bandwidth than that of the resonant waveguide slot array in terms of the array radiation pattern and input VSWR. If the reflections between elements are negligible, a constant phase difference between elements results in a progressive phase shift along the array aperture. The resulting phase front points the peak of the beam to angle θ , which is determined by

$$\sin \theta = \frac{\lambda}{\lambda_g} - \frac{(N-1/2)\lambda}{d} \quad N = 0, \pm 1, \pm 2, \dots \quad (9-19)$$

where d is the inter-element spacing and $|N| > 0$ refers to grating lobes. The influence of element spacing on scan angle is as follows. Assume that d is $\lambda_g/2$ at frequency f_o . The scan angle θ is at 0° . Now assume that $d > \lambda_g/2$ for the same frequency f_o . The beam peak has now moved in angle toward the load end of the waveguide. When the spacing is chosen so that d is less than $\lambda_g/2$, the beam peak now moves in angle toward the feed end of the waveguide. However, given a fixed inter-element spacing, the beam scans toward the load end of the waveguide as the frequency is increased. When the operating frequency is close to the cutoff frequency, grating lobes begin to appear in the radiation pattern of the array. Filling the waveguide with a dielectric material extends the frequency range, and therefore the angle, over which a grating lobe-free beam scan is possible. Hence, the ability to adjust the beam peak to a position around which a frequency scan can occur is important for traveling-wave arrays.

The nonresonant array achieves its large impedance bandwidth by virtue of the phase differences between the reflections from the various slots. The phase differences, which arise from nonresonant spacing, cause the resultant sum of all the reflected waves to be quite small. When the slot spacing is approaching $\lambda_g/2$ and the beam peak is very close to the broadside position, the input VSWR will increase rapidly as the slot admittances add in phase so that the input-impedance magnitude is much larger than unity. For this reason a broadside beam direction is reserved only for resonant slot arrays.

Nonuniform Traveling-Wave Slot-Array Design Some special applications, such as in air traffic control, need the shaped beam to scan over a sector. The aperture illumination of a shaped beam requires, in general, both amplitude and phase variations across the aperture. Therefore it is desirable to know whether and how a linear slot array can produce a shaped beam.

It will be seen in the next section that the aperture illumination amplitude can be controlled by the slot conductances. This is the same as was done with the resonant slot arrays. Varying the slot location along the waveguide and, to some extent, varying slot reactance, can control phase. The latter provides limited phase control and results in a narrow frequency bandwidth. A better method for varying the phase is the use of resonant slots and nonuniform inter-element spacing. The resonant slot conductance or resistance controls the aperture illumination amplitude, while the nonuniform element spacing provides the required phase distribution across the aperture.

The process to determine the locations of individual slots along a waveguide to create a desired aperture excitation is an iterative one. The first iteration is to design an array with uniform spacing where the desired phases at each element are specified. A particular waveguide section will feed a subarray of the whole array. If the phases of the slots that would be part of that waveguide section are all normalized to the slot closest to the load termination, then relative phases for each slot up the waveguide section are known. The next step is to compare those phases to the slot phase excitation provided by the waveguide. The difference between the desired phase and the waveguide excitation is how much phase perturbation is required.

Assume that the synthesized aperture illumination for an array is given by

$$A(d_i) = |A(d_i)| e^{-j\psi(d_i)} \quad (9-20)$$

where A and ψ are the amplitude and phase excitations required at slot d_i . This is a complex version of the slot excitation $A(m, n)$ used in earlier discussions except with the ability to move the slot position. For simplicity, waveguide losses and reflections from the slots are assumed to be negligible. Under these assumptions, the waveguide excitation phase is given by

$$\psi_g(d_i) = k_g d_i + (N - i)\pi \quad (9-21)$$

where i signifies the i th slot, N is the total number of slots in that waveguide section, d_i is the distance from the last slot N to slot i , k_g is the waveguide wave number, and ψ_g is the phase excitation coupled from the waveguide. The phase error is given by

$$\Delta\psi_i = \psi(d_i) - \psi_g(d_i) \quad (9-22)$$

The delta phase error should be rewritten as a $\text{Mod}(\Delta\psi, 2\pi)$. Assuming that $\Delta\psi$ is not large, then it can be represented as

$$\Delta\psi_i = k_g \Delta d_i \quad (9-23)$$

A positive Δd_i represents movement toward the feed. A negative Δd_i represents movement toward the termination end of the waveguide. Once the slots are repositioned, the new slot positions are submitted to the aperture design model to reassess the mutual coupling effects and to see if the new results agree with the modified slot excitations at their new positions. If the phase differences are still too large, the slot repositioning process is repeated. Usually the rate of convergence is quite rapid (two or three times) if the desired illumination phase function is a slowly varying function, such as the phase function for a cosecant-squared-beam aperture. After the slot locations have been determined, the slot resonant conductances can be computed in the same manner as for the uniform traveling-wave array.

If the waveguide losses or the reflections from the slots are not negligible, then the transmission-line model of the slotted waveguide is required to determine the phase of the slot coupling to the waveguide. The simple solutions obtained by neglecting the reflection from the slots and waveguide losses are employed as the first-order approximation in the iteration procedure. The iterative procedure is the same as has been described earlier, but ψ_g and $\Delta\psi$ must be expressed by the transmission-line model to compute the phases associated with the admittance and the slot resonant conductances. The geometry of the slots can then be realized after the slot locations and resonant conductances have been determined.

In general, if the nominal value of the unequal element spacing is larger than one-half free-space wavelength, higher sidelobes will appear in the region far off broadside. Therefore, it is recommended that nominal inter-element spacing be less than one-half waveguide wavelength for the nonuniformly spaced slotted array.

9.4 COMPUTATION METHODS FOR SLOT CHARACTERIZATION

Before the advent of more capable EM modeling tools, extensive analytical and experimental studies were conducted to characterize waveguide-fed slots. Automated test equipment, such as computerized network analyzers, has greatly simplified data recording and processing to enable full S-parameter measurement techniques⁶ to characterize the effects of slot geometry and placement parameters. On the other hand, the cost of conducting elaborate empirical studies is prohibitive, and many recent investigations have focused on improving the computation models of specialized parts such as waveguide *T*-junctions, waveguide-to-waveguide slot coupling, and finite array performance predictions using slot radiators. Few recent publications attempt to develop explicit formulas that predict waveguide-fed slot admittance in the presence of a finite array because these parameters are obtained directly through EM modeling. Commercial software provides design information for waveguide arrays. However, much work still needs to be done to develop modeling tools that can provide an optimized design solution. Still, many waveguide array designers utilize existing formulas for slot admittance to obtain a first order design that might not include all the mutual coupling effects, edge effects, radome scattering effects, etc. Then they utilize numerical optimization techniques to complete the design. This section will focus on the basic waveguide-fed slot conductance (admittance) representations published in earlier works.

Stevenson's Solution

Stevenson⁷ developed his formulas for representing slot characteristics by making the following assumptions: the slot was cut in a perfectly conducting, infinitely thin wall; the width of the slot was much less than its length; the slot length was nearly equal to $\lambda_0/2$; and the slot was radiating over a perfectly conducting ground plane of infinite extent.

Using transmission-line theory and the waveguide modal Green's functions, Stevenson derived the values of the resonant resistance and conductance, normalized to the waveguide impedance, for various slot types along a rectangular waveguide.

Longitudinal Shunt Slots: The conductance of a longitudinal shunt slot (slot a in Figure 9-1) cut in the broad face of a waveguide is given by

$$g = g_1 \sin^2 \left(\frac{u\pi}{a} \right) \quad (9-24)$$

$$g_1 = \frac{2.09a\lambda_g}{b\lambda} \cos^2 \left(\frac{\lambda\pi}{2\lambda_g} \right) \quad (9-25)$$

where λ is the free-space wavelength, λ_g is the guide wavelength, u is the slot displacement from the waveguide centerline, and a and b are the waveguide width and height.

Series Slots: The resistance of the centered inclined/rotated series slot (slot d of Figure 9-1) in the broad face of a waveguide is given by

$$r = \frac{0.131\lambda^3}{ab\lambda_g} [I(\phi) \sin \phi + \frac{\lambda_g}{2a} J(\phi) \cos \phi]^2 \quad (9-26)$$

$$\frac{I(\phi)}{J(\phi)} = \frac{\cos(\pi\xi/2)}{1-\xi^2} \mp \frac{\cos(\pi\zeta/2)}{1-\zeta^2} \quad (9-27)$$

$$\begin{cases} \xi \\ \zeta \end{cases} = \frac{\lambda}{\lambda_g} \cos \phi \pm \frac{\lambda}{2a} \sin \phi \quad (9-28)$$

where ϕ is the slot inclination angle with respect to the centerline of the waveguide.

Narrow-Wall (Edge) Shunt Slots: The conductance of an edge slot on the narrow face (slot c of Figure 9-1) is given by

$$g = \frac{30\lambda^3\lambda_g}{73\pi a^3 b} \left[\frac{\sin \phi \cos \left(\frac{\pi\lambda \sin \phi}{2\lambda_g} \right)}{1 - \left(\frac{\lambda \sin \phi}{\lambda_g} \right)^2} \right]^2 \quad (9-29)$$

where ϕ is the included angle of the slot from vertical.

These equations yield quite accurate results for a single-slot radiator without mutual coupling being included and give no information about the reactive component. However, mutual-coupling effects are not negligible especially with $M \times N$ arrays, and Stevenson's approximations could be off by a large margin.

Variational Technique

Oliner⁸ first formulated an equivalent circuit model for a thick slot using a variational technique. An accurate impedance solution can be obtained by using a slot-aperture field

close to the actual slot field. The method can also account for mutual coupling and provide an estimate for the reactive component of the slot impedance.

Consider a longitudinal shunt slot in the broad face of a rectangular waveguide radiating into free space. By extending Oliner's variational formulation, an explicit impedance expression can be derived in terms of the slot-aperture admittance $Y_r = G_r + jB_r$.⁹

Let the length and the width of the rectangular slot be a' and b' , respectively. The propagation constant and the characteristic admittance of the TE_{10} mode in the waveguide are given by $\kappa = (k^2 - (\pi/a)^2)^{1/2}$ and $Y_0 = \kappa/\omega\mu$, where $k = 2\pi/\lambda$, $\omega = 2\pi f$ is the angular frequency, and μ is the permeability. The rectangular slot on the thick waveguide wall is regarded as a stub waveguide with propagation constant $\kappa' = (k^2 - (\pi/a')^2)^{1/2}$ and characteristic admittance Y_0' . The input admittance at the stub-guide junction can be determined by

$$Y_{rj} = Y_0' \frac{Y_r + jY_0' \tan \kappa' t}{Y_0' + jY_r \tan \kappa' t} \quad (9-30)$$

where t is the thickness or depth of the slot. From the standpoint of the feed waveguide, the equivalent circuit of a displaced longitudinal shunt slot can be represented by a shunt network, as depicted in Figure 9-10. Z_{rj} is the impedance due to the radiating aperture, while X_j is related to the stored power in the feed waveguide. Near resonance, these quantities can be approximated by the variational result.⁹

$$\frac{R + jX}{Z_0} = \frac{Z_{rj} + jX_j}{Z_0} = \frac{a'b'}{2N_s^2} \frac{(Y_{rj} + jB_j)}{Y_0} \quad (9-31)$$

$$N_s^2 = (2/ab) \frac{2\pi^2 b'}{aa'\kappa} \left[\frac{\sin(\pi u/a) \cos(\kappa a'/2)}{(\pi/a')^2 - \kappa^2} \right]^2 \quad (9-32)$$

where u is the displacement of the slot from the center of the waveguide. The junction susceptance B_j is given by

$$B_j = \frac{4b'}{\omega\mu ab} \sum_{m=0, n=0} \left[\cos\left(\frac{m\pi}{2} + \frac{m\pi u}{a}\right) \operatorname{sinc}\left(\frac{m\pi b'}{2a}\right) \right]^2 \frac{\operatorname{Im}(W)}{(\epsilon_m \epsilon_n)} \quad (9-33)$$

FIGURE 9-10 Equivalent network of a longitudinal shunt slot

where

$$\text{sinc}(x) = \frac{\sin(x)}{x}$$

and

$$Q_2(m, n) = \frac{\kappa'^2}{\left[\left(\frac{\pi}{a} \right)^2 - \kappa_{mn}^2 \right]} \quad (9-34)$$

$$Q_3(m, n) = 2 \left(\frac{\pi}{a'} \right)^2 \frac{\left[\left(\frac{m\pi}{a} \right)^2 + \left(\frac{n\pi}{b} \right)^2 \right]}{\left[\left(\frac{\pi}{a'} \right)^2 - \kappa_{mn}^2 \right]^2} \left[\frac{1 + e^{-ja'\kappa_{mn}}}{ja'\kappa_{mn}} \right] \quad (9-35)$$

$$\kappa_{mn} = \left[k^2 - \left(\frac{m\pi}{a} \right)^2 - \left(\frac{n\pi}{b} \right)^2 \right]^{1/2} \quad (9-36)$$

$$\epsilon_n = \begin{cases} 2 & n = 0 \\ 1 & n > 0 \end{cases} \quad (9-37)$$

Im indicates the imaginary part of the complex expression.

Resonance can be defined as the condition in which slot admittance is a real quantity. To compute the slot resonant length, several slot admittances corresponding to several values of a' nearly equal to $\lambda_o/2$ are computed first. The slot resonant length can then be determined by interpolating the length that yields zero imaginary part for the admittance. The preceding solution applies to rectangular slots only. For round-ended slots, the resonant length must be modified by

$$L = a' + Cb'(1 - \pi/4) \quad (9-38)$$

where a' is the resonant length of the equivalent rectangular slot and C is the correction factor.⁹

A similar variational formulation has been applied to compute the impedance of a rotated series slot on the broad side of a rectangular waveguide. The slot rotation angle replaces the slot displacement variable u from the waveguide centerline in the derivation. However, the slow convergent series in the resultant reactance expression requires special numerical treatment. Because field distributions in complicated slot shapes are difficult to obtain, variational solutions for edge slots and folded slots have not been derived explicitly.

Scattering Modal Analysis

Using an approach similar to Frank and Chu's formulation of the E -plane T solution,^{10,11} Montgomery derived the slot-characterization scattering matrices and hence the shunt-slot admittance and series-slot impedance.¹² This scattering modal analysis technique requires a greater computation effort than Stevenson's and the variational solutions.

The slot is assumed to be a stub guide branched out from the main guide where the field in the slot is expressed by a series of stub-guide modal functions. The main-guide field is represented by a series of modal Fourier integrals in which the wave number corresponding to the guide axis is the integration variable. By matching the tangential slot and waveguide field components at the slot aperture, two integral equations are obtained. The expansion coefficients and the scattering parameters can then be determined by solving these two integral equations using the Ritz-Galerkin method. After the expansion coefficients have been computed, the junction scattering matrix of the slot in the waveguide can be calculated. By combining the junction scattering matrix with the reflection coefficient from the radiating slot, the slot equivalent circuit is determined.

This method has been applied to the computation of individual slot characteristics and to the analysis of coupling effects between two slots or between a slot and a waveguide junction. Numerical results of longitudinal-slot parameters computed by the variational method and the scattering modal analysis compare favorably.

Moment Method

The method of moments (MOM) has been applied to characterize a narrow slot in the broad wall of a rectangular waveguide^{13,14} and can be extended to obtain the solution of folded slots in the edge wall. The moment method requires greater computational effort than any of the three other methods discussed here.

Vu Khac and Carson¹³ formulated the slot characterization by shorting out the slot and replacing it with an equivalent magnetic current. The appropriate magnetic Green's functions in the feed guide, inside the slot cavity (taking into account the finite wall thickness), and in free space are employed to derive the basic integral equations. The slot field is expressed as a series of discrete impulse functions. By matching the tangential components at the slot aperture and using the Ritz-Galerkin method, a matrix equation is derived. Then the expansion coefficients are determined by solving the matrix. The computational effort can be greatly reduced by using full-wave basis functions as shown by Lyon and Sangster.¹⁴ The computed results usually closely match the variational solution and experimental results.

When the moment method is applied to characterize the rotated series slots, a slowly convergent series is encountered, as with the variational formulation and the scattering modal analysis. All the matrix elements used in the moment method involve one or two slowly convergent series compared with only one slowly convergent series in the variational technique; therefore, the moment method requires much more computation time.

Method-of-moments (MOM) analysis of slotted-waveguide antennas has progressed rapidly during the past 20 years. Applications include the characterization of broad-wall longitudinal slots, edge-wall inclined slots,¹⁵ *I*-slots,¹⁶ and ridge-waveguide-fed slots.¹⁷ Single slot characterizations are easily extended to finite-array solutions. During the last ten years new numerical techniques in low-frequency methods have been developed to solve large impedance arrays. That makes it possible to model moderately sized arrays exactly.

9.5 DESIGN PARAMETERS

The measured and computed slot characteristics presented in this section, except for the admittance shown in Figure 9-17, are given for a 1.5875-mm wide slot in a standard WR-90 X-band waveguide at 9.375 GHz. This slot will subsequently be referred to as

the *baseline slot*. A planar slotted-waveguide array could be designed by using data presented in this section.

Longitudinal Shunt Slots

Watson,¹⁸ Stegen,¹⁹ and Kaminow and Stegen²⁰ performed extensive empirical studies of isolated longitudinal shunt slots radiating into free space. From the measured data, Stegen found that the ratio of conductance to resonant conductance G/G_m and the ratio of susceptance to resonant conductance B/G_m versus the ratio of slot length to resonant length are independent of the slot displacement off the waveguide centerline. These universal curves of the baseline-slot admittance normalized by the resonant conductance versus slot length normalized by the resonant length are plotted in Figure 9-11. The measured ratio of slot resonant length to wavelength and the measured ratio of slot resonant conductance to waveguide wave admittance versus the slot displacement off the waveguide centerline are shown in Figure 9-12 and Figure 9-13, respectively.

By using the variational result of Eqs. 9-30 through 9-33, the computed slot admittance normalized by the resonant conductance is also shown in Figure 9-11. The aperture admittance of a slot radiating into the half space is approximated by the solution given by Kurss and presented in Oliner.⁸ However, although the computed results agree well with the measured data, the ratios G/G_m and B/G_m versus the normalized slot length L/L_0 are not exactly independent of the slot displacement off the guide centerline.

By using the same technique, the computed slot resonant length and resonant conductance are given in Figure 9-12 and Figure 9-13, respectively, for comparison with the measured results. Note that the round-ended-slot resonant length L_0 is approximated by Eq. 9-38. Choosing C to be 0.64 and comparing the computed and measured results show that the computation method is sufficiently accurate for practical applications.

In airborne radar applications, large arrays of uniformly spaced slots are commonly used. The longitudinal-shunt-slot admittance of a slot in the central region of a large uniform array can be computed by the variational technique.⁹ If the element spacing of a square grid is assumed to be equal to $0.71\lambda_0$, the slot-aperture admittance can be determined by an infinite array of open-ended rectangular waveguides.²¹ The computed normalized

FIGURE 9-11 Admittance of the baseline longitudinal shunt slot versus normalized slot length

FIGURE 9-12 Normalized resonant conductance of the baseline longitudinal shunt slot versus displacement off the waveguide centerline

admittance of the baseline slot in the array is compared with the measured results of the isolated slot in Figure 9-14. The comparison shows that the mutual-coupling effects reduce the slot bandwidth performance.

FIGURE 9-13 Normalized resonant length of the baseline longitudinal shunt slot versus displacement off the waveguide centerline

FIGURE 9-14 Admittance of the baseline longitudinal shunt slot versus normalized resonant slot length. The solid curves are best fit to the computed points. The mutual coupling effects of the array environment narrow the admittance bandwidth of the slot.

By using the same dimensions, the resonant conductance and resonant length of a slot in a large array are shown in Figure 9-12 and Figure 9-13. The mutual coupling effects also affect the slot resonant length as well as the slot resonant conductance. The small change in the slot resonant length in this case may not significantly affect antenna performance. However, an increase of the slot resonant conductance by a factor of 2 usually causes a 2:1 voltage-standing-wave-ratio (VSWR) at the center frequency. This has been observed in slot-antenna arrays designed by using measured single-longitudinal-slot conductances.

Stern and Elliott²² investigated the resonant characteristics of broad-wall longitudinal slots using the MOM formulation. They found that the single-shunt lump-circuit representation for a longitudinal slot is valid only if the slot offset from the waveguide centerline is not too large and that the waveguide height is greater than $\lambda_0/10$.

Based on the sinusoidal representation of the slot aperture field near the first resonance, Elliott²³ improved the small-array design technique to include dielectric-filled slots. An array of magnetic currents derived from the sinusoidal-slot aperture fields replaces the dipole-array solution in the original formulation to account for the external mutual-coupling effects. The internal field formulation is modified accordingly.

The MOM formulation of a finite array of longitudinal slots yields accurate results in comparison with measured data. The single lumped admittance representation of the slots in the MOM solution verifies that the infinite-array solutions shown in Figure 9-12 through Figure 9-14 are accurate for a finite array as small as 25 elements. Figure 9-15 shows the comparison between longitudinal-slot resonant conductances and the resonant lengths computed by the infinite-array approximation and the finite-array MOM results. The nominal array element spacing is $0.71\lambda_0$ in a square lattice. The finite-array results apply to uniform square arrays of N by N elements. Thus infinite-array admittances yield accurate values for large slotted-waveguide arrays.

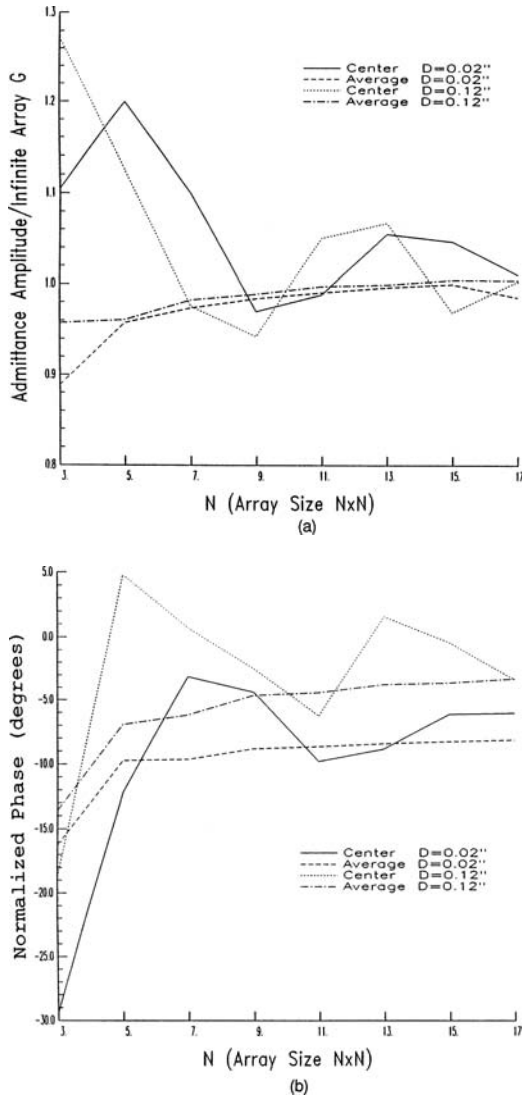

FIGURE 9-15 Slot admittances from a finite array of $N \times N$ elements normalized by infinite array results: (a) admittance amplitude and (b) admittance phase

Edge-Wall Slots

Edge-wall slots are cut into the narrow wall and wrapped around the broad wall of the rectangular waveguide. Folded C- and I-slots are more convenient for edge-wall planar arrays.^{2,3,16,24,25} Recently, several authors derived analytical solutions for narrow-wall slot admittance. These solutions include the inclined-edge slot, C-slot, and I-slot. These slot

types radiate relatively high cross-polarized fields as compared with the broad-wall longitudinal slots. Experimental results must be used to characterize them. Fortunately, strong mutual coupling effects can be measured by a waveguide section with a sufficient number of identical edge-wall slots. Watson¹⁸ has defined the incremental conductance caused by the mutual-coupling effect as the increase in the conductance of a group of resonant, half-wave-spaced, identical edge-wall slots.

For both the linear and *C* edge slots, the resonant conductance may be approximated by

$$G = G_0 \sin^2 \phi \quad |\phi| \leq 15^\circ \quad (9-39)$$

where ϕ is the inclination angle from the vertical. The slot resonant conductance is insensitive to variations in the slot resonant length. Hence, if the incremental conductance is obtained by experiment for one value of angle, Eq. 9-39 can be used to obtain the resonant conductance for other slot inclination angles with reasonable accuracy.

Plotted in Figure 9-16 are the single-slot resonant conductance and the incremental conductance for edge slots cut on the standard WR-90 rectangular waveguide as was measured in Watson.¹⁸ The incremental conductance data are sufficiently accurate for slots in a linear array far removed from the ends. The conductance of the slots near the ends of the array lies between that of the single-slot data and that of the incremental conductance.

The edge-slot admittance, as a function of the depth the slot cut has penetrated into the rectangular-waveguide broad faces, was investigated by Watson.¹⁸ Measurements were performed on a slot that was cut into standard WR-284 waveguide. The admittance for a single 15° slot with a width of 6.35 mm at 2.8 GHz is given in Figure 9-17. These results can be translated to the frequency performance of the edge slot with the conclusion that the frequency bandwidth of edge slots is greater than that of longitudinal shunt slots.

To account for the external field in the inclined-slot analysis, Jan et al¹⁵ modified the 90° wedge Green's function to approximate the thick-edge-wall Green's function. They used a MOM formulation to find the admittance of the inclined narrow-wall slots. The point-matching-technique formulation for the waveguide field usually results in a divergent

FIGURE 9-16 Incremental and single-slot conductance (unmarked dimensions of waveguide section are in inches); frequency = 9.375 GHz, WR-90 waveguide

FIGURE 9-17 Variation of slot admittance with depth of cut; frequency = 2.8 GHz, WR-284 waveguide

series for inclined slots. Nevertheless, their computed results of single slots agreed with the experimental data shown in Figure 9-16 and Figure 9-17 and followed the same trend as computed by Eq. 9-39.

Employing the Galerkin method in the MOM formulation, Yee and Stelletano¹⁶ obtained a MOM solution for symmetric edge-wall *I*-slots on an infinite ground plane. They analyzed each *I*-slot as three rectilinear slots tied together and used sinusoidal basis functions in each rectilinear slot. In contrast to adding a set of junction basis functions, it took advantage of the natural solution to determine the field in the overlapped regions. The computed and measured results show that (1) the *I*-slot can be represented by a shunt admittance with additional shunt capacitance; (2) the cross-polarization isolation of an *I*-slot is about the same as other edge-wall slots (inclined slot, *C*-slot, etc.); and (3) the *I*-slot can radiate a sufficiently large dynamic range of power for practical array designs by changing its cross-branch offset.

Series Slots

The series-slot impedance can be computed by the variational formulation,⁸ the scattering modal analysis technique,¹² or the moment method¹³ as described earlier. By using either the variational formulation or the scattering modal analysis, the slot is first considered as a branched waveguide radiating into the main waveguide. The aperture impedance of the branched waveguide can be determined by assuming a cosine distribution across the slot aperture. The slot-aperture impedance facing the other waveguide is computed in the same manner except that the slot inclination angle is the complementary angle. Properly combining these two solutions yields the series-slot impedance and hence the slot resonant resistance and resonant length. When round-ended series slots are used in the design, the slot resonant length can be determined by setting $C = 1$ in Eq. 9-38.

By using the scattering modal analysis solution, the computed resonant resistance and round-ended resonant length versus the inclination angle for the baseline slot are plotted in Figure 9-18 and Figure 9-19. The input and output waveguides are assumed to be perpendicular to each other for these computed data.

FIGURE 9-18 Normalized resonant resistance versus rotation angle of a baseline inclined series slot

Other Slot Admittance Determination Approaches

Active Slot Admittance Elliott^{26,27} derives two expressions for slot-array active admittances in terms of slot excitation voltages, slot parameters, and the complementary dipole array active impedances. By combining these two expressions with the corresponding dipole array solution, a small-array slot geometry can be specified by using the iterative procedure as described by Elliott.²⁶ The single-slot admittances of a single-slot radiator are used to model the slot admittance characteristics to reduce computational effort.

FIGURE 9-19 Normalized resonant length versus rotation angle of a baseline inclined series slot

This technique is quite accurate for small-array design as demonstrated by Elliott.²⁶ The required computation effort makes this technique unattractive for large-array applications.

Equivalent Self-Admittance Slot equivalent self-admittances can be computed by Eqs. 9-30 through 9-33 by neglecting the edge effects, the small alternating displacements from the guide centerline, the slowly varying illumination, and the small slot-length variation. The slot admittance is determined by either (1) using the equivalent infinite array slot admittance²¹ or (2) by applying Babinet's principle that relates slot aperture admittance to the complementary dipole radiation impedance.²⁸ By using the computed admittance values corresponding to several slot lengths, the resonant conductance and resonant length versus slot displacement similar to that shown in Figures 9-12 and 9-13 can be determined. By combining these design curves with the predetermined slot locations and resonant conductances, the slot-array antenna design is completed.

The computed slot admittances take mutual-coupling effects into account, but neglect edge effects, slot displacements from the guide centerline, nonuniform aperture illumination, and slot-length variation. For large arrays in general, displacements are small, illumination is slowly varying, and edge effects can be neglected. This technique is much more efficient than the active slot admittance method. For a small array, edge effects can be taken into account by several sets of resonant-conductance and resonant-length curves by using the corresponding small-dipole-array solutions. Dipole arrays corresponding to several uniformly alternating displacements can be used to compute the design curves for central elements and edge elements. For practical applications, neglecting alternating displacements in the equivalent dipole array computation results in negligible conductance error and in less than 1.2 percent resonant-length error.

A dielectric cover on the outer waveguide surface is frequently used to protect the antenna from the environment. In general, dielectric loading has little effect on the resonant conductance or resistance of a slot. However, the resonant length is greatly reduced by a dielectric cover and depends on the dielectric constant and thickness. Dielectric-loading effects can be taken into account by using the infinite waveguide array solution.²¹

Incremental Conductance The two methods described earlier are applicable only to longitudinal shunt slot arrays. Analytical solutions have not been as developed for edge-wall slots, and therefore the admittance for a particular slot design must rely on experimentation unless a more elaborate MOM or FEM model is developed.

Many waveguide test sections are required to characterize the slots, including mutual-coupling effects. Each of the test arrays has a sufficiently large number of identical conductance resonant slots so that the edge effects can be neglected. The moving lossy short technique has been successfully applied to the slot-characteristic measurements.^{6,29} Design curves such as resonant conductance and resonant length versus inclination angle for edge slots can be determined as shown in Figure 9-16. Observe that this technique is adequate for large linear-array designs but that inaccurate aperture illumination will be expected when it is applied to small-array designs.

Semiempirical Admittance The three methods discussed earlier are applicable to large arrays or arrays of equally spaced edge-wall shunt slots. Hence the semiempirical admittance technique is generalized to smaller arrays. Basically, the dipole array solution is combined with the following equations to obtain the slot characteristics semiempirically. From Eqs. 9-31 and 9-38, the slot resonant conductance can be expressed by

$$g = U' / \tilde{r} \quad (9-40)$$

where \tilde{r} is the complementary dipole active resistance normalized by the waveguide characteristic impedance and

$$U' = U(a, b, a', b') \begin{cases} \sin^2 \left(\frac{\pi D}{a'} \right) & \text{Longitudinal shunt slots} \\ \sin^2 \phi & \text{Edge-wall shunt slots} \end{cases} \quad (9-41)$$

In general, the change in slot resonant length due to mutual coupling is small, and U is a slowly varying function of a' . Thus, U can be determined approximately by measurement. By combining the approximate value of U , the complementary dipole array solution, the resonant slot conductance, and the slot-location design procedure to be described later, the slot geometry can be determined in the following steps:

Step 1 Measure the single-slot characteristics.

Step 2 By substituting the complementary single-dipole resistance (zero-order approximate value of r) and the measured single-slot resonant conductance into Eqs. 9-40 and 9-41, the values of U for a given slot length and width are determined.

Step 3 By combining the single-slot solution with the equations for specifying the slot locations and resonant conductances such as Eqs. 9-8, 9-9, and 9-21, the first-order design of the slot locations and displacements (or inclination angles) can be determined.

Step 4 The driving-point impedance of the complementary dipole array can be computed by the technique of Carter,²⁸ using the computed slot locations and displacements (or inclination angles) obtained from Step 3 or Step 5 for the lower-order approximation.

Step 5 By substituting the dipole array results from Step 4 into Eqs. 9-40 and 9-41 and combining with slot-location and conductance equations, the next-higher-order approximate solutions for slot locations and displacement (or inclination angles) can be obtained.

Step 6 Repeat Steps 4 and 5 until a satisfactory convergence solution is achieved.

Note that this design procedure yields no information on the resonant lengths of the slots in the array. Fortunately, the slot admittance phase variation introduced by mutual coupling is, in general, small compared with π . Suppose that the single-dipole driving-point impedance is represented by $Z_d' = R_d' + jX_d'$ and the final solution is $Z_d = R_d + jX_d$, then if the guide-wall thickness is negligibly small, the phase difference between the single-slot admittance and the admittance of the slot in the array ψ can be approximated by

$$\tan \psi = 2(X_d' - X_d) / (R_d' + R_d) \quad (9-42)$$

The phase correction can be determined by experimentation or computation of the complementary dipole array by using the ratio of the incremental phase to the incremental slot length near the first resonance. This quantity is almost a constant and depends only on the slot and waveguide geometry.

The preceding iterative procedure has been found to converge rapidly when applied to a planar array of nonuniformly spaced C-shaped slots.

9.6 POWER-HANDLING CAPABILITIES OF SLOTTED-WAVEGUIDE ARRAYS

Slotted-waveguide arrays are required to operate at high-power levels in many applications. In some cases the slot-antenna arrays can handle the high power without undue difficulty at sea-level atmospheric pressure, but they may fail to withstand the power at high altitudes, where atmospheric pressure is much lower. When high-power capacity is required for an airborne antenna, the power-handling capability at the operational altitude must be engineered into the designs.

The power-handling capacity of a slotted-waveguide array depends on both waveguide manifold design and slot design. Following the procedure established by Gilden and Gould,³⁰ the waveguide manifold power-handling capability can be estimated with reasonable accuracy. As an example, consider a standard X-band WR-90 waveguide operating at a frequency of 9.375 GHz. On the basis of Gould's data, the continuous-wave power and the power of a 1- μ s rectangular pulse versus the altitude are shown in Figure 9-20. Observe that the maximum power level that can be handled by the waveguide decreases rapidly when the altitude increases and the waveguide pressure follows atmospheric pressure at altitude. Also note that these results apply to room temperature for a perfectly matched waveguide section. If this is not the case, the pressure at other temperature ρ is required for computing the maximum power level where

$$\rho = \rho_0(293/T) \quad (9-43)$$

T is the absolute temperature ($^{\circ}\text{K}$), and ρ_0 is the pressure at room temperature.

FIGURE 9-20 Power-handling capacity of WR-90 waveguide at 9.375 GHz

The electric field strength E across the slot aperture for a given slot-radiated power P is needed to compute the slot power-handling capacity. The electric field strength across the slot aperture is approximated by

$$E = (\eta_0 / b') \sqrt{P / 2R} \quad (9-44)$$

where R is the complementary dipole driving-point resistance. The baseline slot at 9.375 GHz is used to illustrate the slot power-handling capability. By combining Gilden and Gould's results³⁰ with Eq. 9-43, the maximum continuous-wave and peak power versus the altitude for the baseline slot is computed and shown in Figure 9-21. Equation 9-43 should be used for temperatures other than room temperature.

The power-handling capability can be improved by (1) avoiding capacitive windows and sharp corners in the waveguide manifold, (2) increasing the slot width, and (3) cooling and pressurizing the antenna system. The most effective technique for increasing power-handling capability is to pressurize the waveguide network or just certain waveguide sections that handle the largest power.³¹ If a slot-antenna array is wholly encapsulated in a pressurized housing, the increase in power-handling capability is proportional to the achievable pressure. Occasionally gases, such as nitrogen, Freon, and sulfur hexafluoride (SF_6), are used for pressurization, further increasing power-handling capability through the higher dielectric strength of the gases. The advantage of pressurized systems is that the pressure also keeps out moisture, dust, insects, and other debris that could cause arcing. This approach adds to the complexity of the mechanical design and fabrication of the antenna due to seals and other added equipment. Pressurization does add to the complexity and cost of any design.

FIGURE 9-21 Power-handling capacity of the baseline slot in the planar array

9.7 TOLERANCE AND FABRICATION TECHNIQUES

In practice an antenna will include errors introduced by inaccuracies in the manufacturing process. Manufacturing costs are higher when excessively tight tolerances must be maintained. Thus a systematic allocation of dimensional tolerances is usually a worthwhile part of the design process.

The tolerance for waveguide width can be established by computing the incremental phase per unit change in the manifold and feed waveguide width. To determine the required dimensional tolerance for slots, the incremental conductance (or impedance) per unit change in the slot length from the resonant length is needed. These incremental values per unit change of slot parameters can be determined from given slot parameters discussed in preceding sections. Listed in Table 9-1 are the incremental phases of baseline shunt and series slots and the *S*-band edge slot due to the decrease of 1 percent slot length from resonant lengths. Note that the tolerance requirement for edge-slot arrays is less critical than for other slot arrays.

The difference in the incremental phase change indicates that the mutual-coupling effects reduce the longitudinal shunt-slot frequency-bandwidth performance and increase tolerance requirements. Sidelobe performance can be greatly degraded by a 1 percent variation in the slot length in a planar array of longitudinal shunt slots.

Fabrication of the commonly used edge-slot array is quite different from that of other slot arrays. Since the edge slot is cut into the narrow wall and wrapped around the broad faces of a rectangular waveguide, an edge-slot array can be easily fabricated by cutting (sawing) the slots at the proper angle and depth. The results are, in general, quite good. To generate a planar edge-slot array, slotted-waveguide sections are manifolded and assembled side by side to form a planar aperture.

To fabricate a planar array of longitudinal shunt slots or edge-wall folded shunt slots, a milling machine may be used to cut the slot on a thin, flat plate (face plate) such as shown in Figure 9-18. The back plate is milled out of a thick metal plate. Two narrow walls of the shunt and series waveguides are fabricated on the opposite sides of the metal plate, and the series slots are cut on the common walls of the shunt and series guides. Assembling the back plate to the face plate forms the shunt waveguides. Attaching the feed covers to the back plate forms the series waveguides.

The common techniques for assembling the face plate to the back plate array of broad-wall slots are

- **Welding** Both laser welding and electron-beam welding can be used to join the face plate to the back plate. Electron-beam welding has been successfully applied to manufacture antennas made of magnesium. Because of the inherent properties of aluminum, applying the electron-beam welding technique to this metal in assembling the flat-plate antenna requires additional investigative effort. Laser welding of the face plate to the back plate is possible, but the process is better suited to welding very thin metal cross sections and has limited application to flat-plate antennas.

TABLE 9-1 Incremental Phase Change of Slot with 1 Percent Change in Slot Length from Resonant Length

Longitudinal shunt slot		Edge slot	
Single	Coupled	Rotational series slot	Coupled
8.1°	19.3°	17.1°	2.7°

- **Brazing** Dip brazing has been widely used to secure two aluminum objects together. Many aluminum slotted-waveguide arrays are assembled by using dip brazing. The disadvantages of this technique are that the residue deposits left in the waveguides and on the slots, and the overall material shrinkage must be accounted for. The fluxless-brazing technique for joining the aluminum face and back plates together in a retort with inert atmosphere has been investigated with successful results.³²
- **Bonding** There are three commonly used bonding techniques: (a) thin-film bonding, (b) conductive-epoxy bonding, and (c) diffusion bonding. Thin-film bonding and conductive-epoxy bonding are quite popular in flat-plate-antenna applications.

Other techniques such as screw fasteners and twist tabs have been employed to join the face and back plates together. These two methods are either limited as to application or less accurate, adversely affecting antenna performance when compared with the preceding three assembling techniques. These approaches are prone to RF leakage.

The linear array is subject to fewer tolerance and assembly problems than the planar array. To fabricate and assemble a planar array such as the flat-plate antenna, both before and after the process of joining the face and back plates together, attention must be paid to keep the antenna aperture flat and the plates aligned accurately. A $0.01\lambda_o$ warping of an antenna can significantly degrade sidelobe performance, and a $0.007\lambda_o$ misalignment of the front and back plates will produce a grating-lobe level higher than -20 dB. Slot-length tolerance depends on the desired radiation performance.

Although a slot-antenna array can be designed and fabricated by using the design information given in this chapter, antenna performance may be less than expected. Some of the second-order effects, such as the slot alternating displacements, alternating inclined angles, edge effects, nonuniform aperture illumination, slot-length errors, and internal coupling through higher-order waveguide modes have not been addressed. The combined effects of neglecting second-order effects, manufacturing tolerances, and inaccurate manifold design usually significantly degrade practical slotted-array performance. For instance, a -35 -dB sidelobe-level array design may have only -28 -dB sidelobes in practice. Thus a thorough error analysis is recommended to define dimensional tolerances and to determine aperture illumination errors. Normally, overdesign is used to allow for design and manufacturing deficiencies, the degree of overdesign usually being determined by experience. Note that some of the degradation factors will be more noticeable for a -30 -dB sidelobe-level array design than for a -20 -dB design.

10.1 INTRODUCTION

The two types of traveling-wave antennas discussed in this chapter are illustrated in Figure 10-1. In Figure 10-1a, a *surface wave* (also called a *trapped wave* because it carries its energy within a small distance from the interface) is launched by the feed F and travels along the dielectric rod to the termination T . Since a surface wave radiates only at discontinuities, the total pattern of this antenna (normally end-fire) is formed by the interference between the feed and terminal patterns.¹ The dielectric material could alternatively be an artificial one, e.g., a series of metal disks or rods (the Yagi-Uda antenna). On the other hand, discontinuities can be placed all along the surface-wave structure, producing radiation in the manner of a slotted waveguide, except that the wave propagates on an open, not a shielded, guide. The array of dipoles proximity-coupled to a two-wire transmission line in Figure 10-1b illustrates this second antenna type; here we are evidently using the term *surface wave* loosely to designate any wave mode that propagates along an open interface without radiating.

FIGURE 10-1 Surface-wave-antenna types: (a) dielectric rod and (b) array of proximity-coupled dipoles (thin lines are dielectric supports)

Two closely related antenna structures are discussed in other chapters: the helix (which involves a surface wave in one of its modes of operation—Chapter 12) and the frequency-independent antennas (Chapter 13). The short Yagi-Uda, in whose design surface waves play no role, is covered in Chapter 3. An additional discussion of surface wave antennas can be found in Zucker.²

Surface-wave antennas lend themselves to flush, or at least low-silhouette, installation. Their gain normally does not exceed 20 dB, and control over their pattern shape (including sidelobes) is *limited*. Bandwidth is generally narrow. Frequency coverage extends from the popular Yagi-Udas at very high frequencies (VHF) to printed microwave (and millimeter-wave) antennas. By contrast, arrays excited by surface waves produce patterns that can in principle produce as high gain and be controlled as accurately as the patterns of nonresonant slot arrays.

10.2 PROPERTIES AND MEASUREMENT OF SURFACE WAVES

For design purposes, a surface wave is sufficiently characterized by one of its parameters, for example, the wavelength in the direction of propagation along the interface. The various parameters will now be defined and formulas given for their interrelationship; it will then be shown how they can be calculated if the surface impedance is known or how they can be determined by measurements.

Interrelationship of Parameters

The governing relation is the separability condition for the wave equation. In rectangular coordinates (see Figure 10-2a),

$$k_x^2 + k_y^2 + k_z^2 = k^2 \quad (10-1)$$

FIGURE 10-2 Geometries for surface-wave propagation over dielectric sheets: (a) Infinite-plane sheet-on-metal, (b) Rectangular duct, (c) Axial-cylindrical rod, (d) Radial-cylindrical sheet-on-metal, (e) Azimuthal-cylindrical or spherical cap. Heavy lines indicate metal surfaces. Arrows point in the direction of propagation.

where the k 's, called *wave numbers*, are in general complex—for example, $k_x = \beta_x - j\alpha_x$, with β_x the phase constant in radians per unit length (inches, centimeters, or meters), and α_x the attenuation in nepers per unit length. The wave number k is that of the medium in which the wave travels, $k = \omega\sqrt{\epsilon_0\mu_0}$, with ω the angular frequency, ϵ_0 the dielectric constant, and μ_0 the permeability. In air, k is pure real; it is related to the wavelength λ by $k = \beta = 2\pi/\lambda$ and to the phase velocity of light c by $k = \omega/c$. Similarly, the phase constant β_z along the surface is related to the surface wavelength λ_z by $\beta_z = 2\pi/\lambda_z$ and to the surface phase velocity v_z by $\beta = \omega/v_z$. The following ratios are therefore equivalent:

$$\frac{\beta_z}{k} = \frac{\lambda}{\lambda_z} = \frac{c}{v_z} \quad (10-2)$$

When this ratio is greater than 1, we speak of a “slow” wave (i.e., slower than light, because $v_z < c$); when less than 1, of a “fast” wave ($v_z > c$). The surface wavelength λ_z of slow waves is shorter than λ ; that of fast waves, longer than λ (as in shielded waveguide).

A *surface wave* is one that propagates parallel to the interface and decays vertically to it; that is, the phase constant β_x is zero, and $k_x = -j\alpha_x$ (pure attenuation), with α_x positive. Assume first that the wave extends indefinitely in the transverse direction so that $k_y = 0$ (see Figure 10-2a). Equation 10-1 requires that k_z be pure real; that is, there can be no attenuation in the direction of propagation, and we obtain the simple but basic relation

$$\beta_z^2 = k^2 + \alpha_x^2 \quad (10-3a)$$

or equivalently, by using Eq. 10-2,

$$\frac{\lambda}{\lambda_z} = \frac{c}{v_z} \sqrt{1 + \left(\frac{\alpha_x \lambda}{2\pi}\right)^2} \quad (10-3b)$$

FIGURE 10-3 Phase and amplitude contours of a plane surface wave. (a) Solid lines indicate constant-phase fronts; dashed lines, constant-amplitude fronts; shaded region shows amplitude decay. (b) Solid lines indicate height x/λ above surface of 3-dB, 10-dB, and 25-dB constant-amplitude or power contours as a function of relative surface wavelength λ/λ_z (use left-hand ordinate); numbers in parentheses refer to the percentage of total energy carried by the surface wave between the interface and each contour. The dashed line indicates the relation between relative surface wavelength and vertical attenuation $\alpha_x \lambda$ according to Eq. 10-3b (use right-hand ordinate).

from which it follows that this is a slow wave. Equation 10-3b is plotted as the dashed line in Figure 10-3b. Slower-than-light surface waves are used chiefly in end-fire antenna design (see Sections 10.3 and 10.4). Figure 10-3a illustrates constant-phase and constant-amplitude fronts, which are at right angles to each other provided only that the medium above the interface is lossless. (Ohmic losses in the surface produce a slight forward tilt in the phase front and a small α_x .) The more closely the surface phase velocity approaches that of light, the smaller is α_x (see Eq. 10-3b) and the larger, therefore, the vertical extent of the surface wave in Figure 10-3a.

All components of the total electromagnetic field of the surface wave, for example, E_z , are of the form

$$E_z(x, z, t) = E_z e^{-\alpha_x x} e^{-j\beta_z z} e^{j\omega t} \quad (10-4)$$

The vertical decay of the E_z , E_x , and H_y components of a TM surface wave ($H_z = 0$) is shown in Figure 10-4a, and the composite electric field lines over a full wavelength interval (longitudinal section) in Figure 10-4b. It can be shown that E_z is in phase with H_y , E_x in phase quadrature. The first two components therefore carry all the power along the interface, while E_x and H_y form a vertically pulsating storage field. The dielectric slab-on-metal below the interface in Figure 10-4 is used as an example. Since the form of Eq. 10-4, and thus of the surface-wave field lines, does not depend on the detailed structure of the medium below the interface, a multilayer dielectric or a corrugated sheet, etc., could have been shown equally well.

FIGURE 10-4 Surface-wave field structure above interface. (a) TM-wave components on plane surface. (b) Composite electric field lines over a one-wavelength interval (arrow points in the direction of propagation). (c) Composite electric field lines of HE_{11} wave on an axial-cylindrical surface (cross section). Dashed line shows the electric-image plane (see Section 10.4).

The field (or power) decay in decibels is plotted as a function of height x/λ above the surface in Figure 10-3b (based on Eq. 10-3a). If we assume a relative surface wavelength λ/λ_z (or relative phase velocity c/v_z) equal to 1.1, for example, the field at height $x = \lambda$ has decayed by 25 dB below its value at the interface.

Assume next that two parallel walls are erected normal to the surface, forming a duct in the z direction (see Figure 10-2b). (Examples other than the dielectric-loaded channel in this figure are the channel with a corrugated bottom and the trough guide.) The transverse wave number is fixed by the duct width w as in conventional waveguide theory; from Eq. 10-1 we now have, instead of Eq. 10-3a,

$$\beta_z^2 = k^2 + \alpha_x^2 - \left(\frac{n\pi}{w}\right)^2 \quad n = 0, 1, 2, \dots \quad (10-5a)$$

If $n = 0$ (no variation in y direction), Eqs. 10-3, and therefore also Figure 10-3b, still apply. If $n = 1$ (half a sinusoid in y direction),

$$\frac{\lambda}{\lambda_z} = \frac{c}{v_z} = \sqrt{1 + \left(\frac{\alpha_x \lambda}{2\pi}\right)^2 - \left(\frac{\lambda}{2w}\right)^2} \quad (10-5b)$$

Since the second term is usually smaller than the third, it follows that the wave is usually, though not necessarily, faster than light. Fast as well as slow surface waves can be used to excite arrays of discrete elements. The field and power decay still follows Figure 10-3a and b, provided that the abscissa in Figure 10-3b is relabeled $\sqrt{(\lambda/\lambda_z)^2 + (\lambda/2w)^2}$ to account for the difference between Eqs. 10-3b and 10-5b. The heights x/λ corresponding to the 25-dB contour in Figure 10-3b are useful for estimating the extent to which the duct walls, which theoretically must be infinite in height, may be lowered without perturbing the surface wave.

Surface-wave geometries other than rectangular are shown in Figure 10-2c-e. The separability condition for the wave equation in axial- and radial-cylindrical coordinates (Figure 10-2c and d) reads

$$k_r^2 + k_z^2 = k^2 \quad (10-6)$$

(note that k_θ does not appear), which is formally identical with Eq. 10-1 for the case $k_r = 0$. The interrelationships of the surface-wave parameters given in Eqs. 10-3 still hold if k_r is substituted for k_z . Above the surface, the field components decay like Hankel functions; in the axial-cylindrical case, for example,

$$E_z(r, z, t) = E_z H_0^{(2)}(\alpha_r r) e^{-j\beta_z z} e^{j\omega t} \quad (10-7)$$

The circumferential field dependence in the case of the HE_{11} mode—the one of principal interest in this geometry—is one full sinusoid. Composite E lines for this *hybrid* wave (so called because of the presence of both E_z and H_z) are shown in Figure 10-4c. [The structure inside the circular interface could equally well be a metal rod with a dielectric mantle, an array of circular disks (cigar antenna), or even an array of dipoles (Yagi-Uda).] For large radii, the Hankel function is asymptotic to the exponential, and Eq. 10-7 differs negligibly from Eq. 10-4. As a consequence, the 25-dB contours in Figure 10-3b still hold and the 10-dB contours nearly so; these curves are useful in estimating the degree of coupling between adjacent end-fire line sources. In the radial-cylindrical case, the field components decay exponentially away from the surface so that Figure 10-3b applies exactly. But the constant-amplitude fronts will now no longer be parallel to the surface because the field components decay radially like Hankel functions (asymptotically like $1/\sqrt{r}$), bringing the fronts closer to the surface with increasing r .

In the azimuthal-cylindrical or spherical case, it can be shown that the wave numbers are always complex so that these surface waves are no longer completely trapped. Because the radius of curvature is usually large, it is convenient to treat azimuthal waves as a perturbation of Eqs. 10-3 for flat surfaces.

Calculation of Surface-Wave Parameters

Surface waves are modes on unshielded waveguides. As in the case of shielded waveguides, the boundary-value problem is often conveniently stated in terms of the *transverse resonance condition*, which requires that the equivalent network of a transverse section through the waveguide be resonant.³ With Z_x the impedance looking straight up from the interface and Z_s the surface impedance looking straight down, the resonance condition reads

$$Z_x + Z_s = 0 \quad (10-8)$$

Z_x depends on the geometry and the mode; in rectangular coordinates,

$$Z_x = \frac{k_x}{\omega \epsilon_o} \quad \text{for TM waves} \quad (10-9a)$$

$$Z_x = \frac{\omega \mu_o}{k_x} \quad \text{for TE waves} \quad (10-9b)$$

In the case of a surface wave, $k_x = -j\alpha_x$; Z_x is therefore capacitive in Eq. 10-9a and inductive in Eq. 10-9b. It follows from Eq. 10-8 that the TM surface wave requires an inductive surface, $Z_s = jX_s$, and the TE surface wave a capacitive surface, $Z_s = -jX_s$ (X_s positive). Equation 10-8 now reads

$$\frac{\alpha_x}{k} = \frac{X_s}{R_c} \quad \text{for TM waves} \quad (10-10a)$$

$$\frac{\alpha_x}{k} = \frac{R_c}{X_s} \quad \text{for TE waves} \quad (10-10b)$$

where $R_c = \sqrt{\mu_o \epsilon_o} = 377 \Omega$, β_z or λ / λ_z follows immediately from Eqs. 10-3.

Knowledge of the surface impedance thus solves the boundary-value problem. It is instructive to calculate this impedance for two simple cases: surface waves on a dielectric slab-on metal and on a corrugated-metal sheet. Looking down from the air-dielectric interface in Figure 10-2a, we see a dielectric-loaded region short-circuited at the end. By using transmission-line theory, assuming that the wave is TM, and noting that a wave that is TM in the direction of propagation is also TM transverse to it,

$$X_s = \frac{k_x}{\omega \epsilon_1} \tan k_x d \quad (10-11)$$

where k_x is the vertical wave number in the slab of dielectric constant ϵ_1 . Since X_s must be positive real, $k_x = \beta_x$. (We could now write the field components below the interface in the form of Eq. 10-4, with a sinusoidal variation in x replacing the exponential decay; the field configuration below the interface, however, is rarely of interest to the engineer.) Substitution of Eq. 10-11 in Eq. 10-10a gives one equation in two unknowns, α_x and β_x . α_x is a function of β_z through Eq. 10-3a; β_x can also be expressed as a function of β_z , since Eq. 10-1 reads

$$\beta_x^2 + \beta_z^2 = k_1^2$$

in the dielectric medium ($k_1 = \omega \sqrt{\mu_1 \epsilon_1}$). The solution⁴ shows that the lowest TM mode has no cutoff and that the phase velocity of the surface wave lies between c and $c\sqrt{\epsilon_1/\epsilon_0}$, approaching the free-space velocity in air for very thin sheets and the free-space velocity in the dielectric for thick sheets (numerical results are in Section 10.4). The analysis for a TE wave uses Eq. 10-10b and results in a lowest mode that does have a cutoff. It is worth pointing out that below cutoff a surface wave does not become evanescent but ceases to exist altogether.

The interface of the corrugated-metal sheet (see Figure 10-5) is an imaginary plane through the top of the teeth. X_s is zero over the teeth and equals $R_c \tan kd$ over the groove, which are short-circuited parallel plate transmission lines (inductive in the range $0 < kd < \pi/2$). If there are many grooves per wavelength, the surface impedance over the teeth and grooves may be averaged; that is, $X_s \equiv [g/(g+t)]R_c \tan kd$. Substitution in Eq. 10-10a gives one equation in one unknown. The results of this approximation turn out to be good provided there are at least five grooves per wavelength. A more exact calculation takes into account the higher-order (below-cutoff) modes at the mouth of the grooves, which produce higher-order waves along the interface that modify the field lines sketched in Figure 10-4a and *b* only in the close vicinity of the teeth.

Measurement of Surface-Wave Parameters

In the case of surface waves, a vertical metal plate large enough to reflect at least 90 percent of the incident energy (use Figure 10-3b to determine the minimum size) produces deep nulls

FIGURE 10-5 Corrugated-metal surface. Arrow points in the direction of propagation.

at half-wavelength intervals along the surface. Because of turbulence in the aperture field near the feed, measurements should be made at a minimum distance from the feed given by

$$d_{\min} \cong \frac{0.17\lambda}{(\lambda/\lambda_c) - 1}$$

If the frequency is so low that reflector size becomes a problem, the distance between nulls is found by feeding the probe signal into a phase-comparison circuit (using magic T and attenuator) that measures the traveling-wave phase with respect to a reference signal.

The probe used in these measurements should have a small cross section so as not to perturb the field. It needs chokes to suppress antenna currents on its outer conductor, and it must couple only into the E or the H field, with good discrimination against the unwanted one. A coaxially fed monopole or a waveguide horn pinched at the mouth (with dielectric loading to keep it above cutoff)⁵ is very satisfactory; loops and horizontal dipoles, less so. The distance between probe and aperture should be as small as possible without perturbing the aperture field, and it should be held constant by providing a rigid probe carriage.

10.3 SURFACE-WAVE ANTENNAS: DESIGN PRINCIPLES

Radiation of Surface-Wave Antennas

Before presenting design principles (for optimum gain, beamwidth, sidelobe level, and bandwidth), it is useful to examine how surface-wave antennas radiate. Two typical structures are shown in Figure 10-6. The feed F (consisting of a monopole and reflector in Figure 10-6a and of a circular or rectangular waveguide in Figure 10-6b) couples a portion of the input power into a surface wave, which travels along the antenna structure to the termination T , where it radiates into space. The ratio of power in the surface wave to total input power (efficiency of excitation) is usually between 65 and 75 percent. Power not coupled into the surface wave is directly radiated by the feed in a pattern resembling that radiated by the feed when no antenna structure is in front of it.

FIGURE 10-6 Surface-wave antenna structures: (a) Yagi-Uda (row of monopoles) on ground plane, excited by dipole-reflector combination; (b) Dielectric rod, excited by circular or rectangular waveguide (broad wall in plane of paper)

The tapered regions in Figure 10-6 serve diverse purposes. The *feed taper* increases the efficiency of excitation and also affects the shape of the feed pattern. The *body taper* (extending to point P in Figure 10-6b) suppresses sidelobes and increases bandwidth. Because a reflected surface wave spoils the pattern and bandwidth of the antenna, a *terminal taper* is employed to reduce the reflected surface wave to a negligible value.

The surface wave illuminates the terminal aperture (plane perpendicular to the antenna axis through T) in a circular region whose radius increases as the transverse attenuation of the surface wave diminishes or, equivalently, as the surface phase velocity approaches that of light (Eq. 10-3b). The larger the illuminated region, the higher the gain produced in the radiation pattern. Since the surface-wave phase front lies in the aperture plane, the pattern peaks in the end-fire direction. A simple but only approximate expression^{2,6} for the terminal radiation pattern $T(\theta)$ is

$$T(\theta) \cong \frac{1}{(\lambda/\lambda_z) - \cos \theta} \quad (10-12)$$

where θ is the angle off end-fire and λ_z is the surface wavelength at T (just to the left of the terminal taper, to be precise). This pattern has neither nulls nor sidelobes and, as expected, falls off more rapidly the closer λ/λ_z is to 1. More accurate expressions^{2,7-9} and an experimental determination¹⁰ indicate that the pattern is actually about 20 percent narrower than in Eq. 10-12. The dashed line in Figure 10-7 shows this corrected terminal radiation pattern for $\lambda/\lambda_z = 1.08$, which is the optimum relative phase velocity for a maximum-gain antenna 4λ long (Eq. 10-14b).

The radiation pattern of the feed shown in Figure 10-6a is quite broad (approximately a cardioid in polar coordinates). In combination with the terminal radiation $T(\theta)$, it produces the total surface-wave antenna pattern, shown by the solid line in Figure 10-7 (experimental data for antenna length $\ell = 4\lambda$, $\lambda/\lambda_z = 1.08$). In the vicinity of end-fire, the terminal pattern predominates; as θ increases, interference with the feed pattern first narrows the beam and then produces a sidelobe at 35° ; beyond 45° the feed pattern predominates. Patterns of all surface-wave antennas adjusted for maximum gain look like those in Figure 10-7, except that for antennas longer than 4λ the pattern spreads less in θ (first sidelobe closer to end-fire than 35°) and for shorter structures it spreads more. The field beyond the first sidelobe falls off more rapidly the larger the end-fire gain of the feed radiation.

The curves in Figure 10-7 are for the H plane, in which the element pattern of the Yagi-Uda monopoles (see Figure 10-6a) is omnidirectional. In the E plane, $T(\phi)$ (ϕ is the angle off end-fire) is narrowed by multiplication with the E -plane element factor (a dipole pattern modified by the effects of mutual impedance), which for $\phi < 60^\circ$ approximates $\cos \phi$ and then decays more gradually (no null at $\phi = 90^\circ$). The total pattern in the E plane is therefore also narrower than in the H plane, and sidelobes are lower by 2 to 3 dB.

In the case of the HE_{11} mode on a dielectric rod (see Figure 10-6b), the E - and H -plane element factors, and consequently the beamwidths and sidelobe levels, are more nearly the same. The sidelobe level is now usually *higher* by 0.5 to 1.5 dB in the E plane than in the H plane, the precise amount depending on the relative shape of the E - and H -plane feed pattern.

FIGURE 10-7 Radiation pattern of 4λ -long surface-wave antenna adjusted for maximum gain in accordance with Eq. 10-14b ($\lambda/\lambda_z = 1.08$). $T(\theta)$ is the H -plane pattern of the surface-wave distribution in the terminal plane. For comparison, $\sin \xi/\xi$ is also shown (shaded region).

Instead of being regarded as a combination of feed and terminal radiation, the surface-wave antenna pattern can be viewed as an integral over the field distribution along the antenna structure. What this distribution looks like can be seen in Figure 10-8: the amplitude $A(z)$ along the row of monopoles (see Figure 10-6a) starts with a hump near the feed and flattens out as the surface wave peels itself out of the near field of feed and feed taper. The surface wave is well established at a distance ℓ_{\min} from the feed where the radiated wave from the feed, propagating at the velocity of light, leads the surface wave by about 120° :

FIGURE 10-8 Amplitude $A(z)$ of field along the surface-wave antenna structure

$$\ell_{\min} k_z - \ell_{\min} k = \frac{\pi}{3} \quad (10-13)$$

The location of ℓ_{\min} on an antenna designed for maximum gain is seen in Figure 10-8 to be about halfway between feed and termination. Since the surface wave is fully developed from this point on, the remainder of the antenna length is used solely to bring feed and terminal radiation into the proper phase relation for maximum gain. (In the absence of a feed taper, ℓ_{\min} occurs closer to F and the hump is higher.)

Were there no hump at all, the surface-wave antenna would radiate the familiar $\sin \xi/\xi$ pattern [$\xi = (\pi/\lambda)(\lambda/\lambda_z - \cos \theta)$] produced by constant-amplitude illumination. This pattern is shown for comparison in Figure 10-7 (shaded region); it is an unnatural pattern for parasitically excited antennas, which necessarily have feed turbulence.

Low-sidelobe and broadband designs require tapers that extend over a substantial part of the antenna (see Figure 10-6b). Although the field along one particular taper has been examined in detail,^{11,12} the effect of tapers on the total radiation pattern is not well understood. When the taper is very gradual, the phase velocity at each point has the value we would expect from the local surface impedance; when it is sharp, a leaky wave which fills in the minima of the pattern, widens the beam and reduces sidelobes is produced.

Design for Maximum Gain

The phase velocity along the antenna and the dimensions of the feed and terminal tapers in the maximum-gain design of Figure 10-6a must now be specified.

If the amplitude distribution in Figure 10-8 were flat, maximum gain would be obtained by meeting the Hansen-Woodyard condition (strictly valid only for antenna lengths $\ell \gg \lambda$), which requires the phase difference at T between the surface wave and the free-space wave from the feed to be approximately 180° :

$$\ell k_z - \ell k = \pi$$

or, equivalently,

$$\frac{\lambda}{\lambda_z} = 1 + \frac{\lambda}{2\ell} \quad (10-14a)$$

which is plotted as the upper dashed line in Figure 10-9.

Since the size and extent of the hump are a function of feed and feed-taper construction, the optimum terminal phase difference for a prescribed antenna length cannot easily be calculated.

FIGURE 10-9 Relative-phase velocity $c/v = \lambda/\lambda_z$ for maximum-gain surface-wave antennas as a function of relative antenna length ℓ/λ . HW = Hansen-Woodyard condition, Eq. 10-14b; EP = Ehrenspeck and Poehler experimental values, Eq. 10-14b; 100 percent = idealized perfect excitation, Eq. 10-14c.

Experimental work on Yagi-Uda antennas (but without feed taper) by Ehrenspeck and Poehler¹³ and Ehrenspeck¹⁴ has shown that the optimum terminal phase difference lies near 60° for very short antennas, rises to about 120° for ℓ between 4λ and 8λ , then gradually approaches 180° for the longest antenna measured (20λ). Therefore

$$\frac{\lambda}{\lambda_z} = 1 + \frac{\lambda}{p\ell} \quad (10-14b)$$

with p starting near 6 for $\ell = \lambda$ and diminishing to approximately 3 for ℓ between 3λ and 8λ and to 2 at 20λ . This relation is plotted as the solid curve in Figure 10-9. In the presence of a feed taper, the optimum λ/λ_z values lie slightly below this curve.

If the efficiency of excitation is very high, interference between feed and terminal radiation is of minor importance, and the antenna need just be long enough so that the surface wave is fully established; that is, $\ell = \ell_{\min}$ in Figure 10-8. From Eq. 10-13,

$$\frac{\lambda}{\lambda_z} = 1 + \frac{\lambda}{6\ell} \quad (10-14c)$$

which is plotted as the lower bound of the shaded region in Figure 10-9.

Because feeds are more efficient when exciting slow surface waves than when the phase velocity is close to that of light, the solid line starts near the lower bound and ends at the upper. As long as λ/λ_z falls within the shaded region, its precise adjustment is not critical; with $\ell = 4\lambda$ and in the presence of a feed taper, the gain drops only 1 dB if λ/λ_z lies on the dashed lower bound instead of just below the solid upper bound.

Although this technique for maximizing the gain has been strictly verified only for Yagi-Uda antennas, data available in the literature on other structures suggest that optimum λ/λ_z values lie on or just below the solid curve in all instances. To produce these optimum values, the dependence of λ/λ_z on the structural parameters of the antenna must be calculated, measured, or sought in the literature.

The feed taper should begin at F with λ/λ_z between 1.2 and 1.3 and extend over approximately 20 percent of the full antenna length. Its exact shape is not important as long as a smooth transition is made to the main body of the antenna. The terminal taper should be approximately 0.5λ long, and to match the surface wave to space, λ_z at the end

of the taper should be as close as possible to λ . In the case of a polyrod ($\epsilon = 2.56$), for example, Figure 10-16 shows that λ_z is reasonably close to λ when

$$d/\lambda = 0.23$$

and the end of the rod is therefore blunt rather than pointed.

The *gain* above an isotropic radiator of a long ($\ell \gg \lambda$) uniformly illuminated end-fire antenna whose phase velocity satisfies Eq. 10-14a was shown by Hansen and Woodyard to be approximately

$$G \equiv \frac{7\ell}{\lambda}$$

If the design is based on the optimal phase velocities and taper dimensions just described, the gain for ℓ between 3λ and 8λ is

$$G \equiv \frac{10\ell}{\lambda} \quad (10-15)$$

which is 1.5 dB above the Hansen-Woodyard gain. For shorter lengths the gain may be 30 percent higher; for longer lengths, the proportionality factor slowly decreases because of ohmic loss and the difficulty of designing an efficient feed. Maximum gains reported in the literature are plotted in decibels as a function of ℓ/λ in Figure 10-10 (solid-line margin of shaded region marked "Gain"). These gains involve a slight degree of superdirectivity but not enough to produce excessively narrow bandwidths or high ohmic loss.

FIGURE 10-10 Gain and beamwidth of a surface-wave antenna as a function of relative antenna length ℓ/λ . For gain (in decibels above an isotropic source), use the right-hand ordinate; for beamwidth, the left-hand ordinate. Solid lines are optimum values; dashed lines are for low-sidelobe and broadband design.

The half-power *beamwidth* BW of a maximum-gain design is approximately

$$\text{BW} = 55 \sqrt{\frac{\lambda}{\ell}} \text{ degrees} \quad (10-16)$$

which lies just above the lower (solid-line) margin of the shaded region marked “Beamwidth” in Figure 10-10. Equation 10-16 gives an average figure, the beamwidth usually being slightly narrower in the *E* plane and slightly wider in the *H* plane.

The *sidelobe* level, for ℓ between 3λ and 8λ , is about 11 dB in the *H* plane and 10 or 14 dB in the *E* plane of a dielectric rod or Yagi-Uda, respectively (cf. above). For shorter antennas the sidelobes are somewhat higher; for longer antennas, lower.

The *bandwidth* within which the gain drops at most 3 dB is between ± 10 percent and ± 15 percent. Below the design frequency, gain slowly decreases as beamwidth widens; above it, the pattern deteriorates rapidly as the main beam splits and sidelobes rise.

By comparing Eq. 10-15 with the gain of a paraboloidal dish (equal sidelobe level is assumed), the surface-wave-antenna length is found to be related to the diameter d of an equal-gain dish by

$$\frac{\ell}{\lambda} \cong \left(\frac{d}{\lambda} \right)^2 \quad (10-17)$$

This trade-off between a broadside and an end-fire structure becomes very disadvantageous to the latter as ℓ/λ increases, and surface-wave antennas longer than 10λ are rarely used. This limits the gain of surface-wave line sources in practice to 20 dB. (Arrays of line sources and end-fire area sources are practical for much higher gains.)

The gain predicted by Eq. 10-15 is for feeds of the type shown in Figure 10-6, with radiation patterns that are not very directive. Increasing the feed directivity increases the total antenna gain. For feeds whose radial extent is not much larger than the antenna cross section, it has been found experimentally¹⁵ that a 1- or 2-dB increase in the end-fire gain of the feed produces an approximately equal increase in the total antenna gain. If the feed is much larger than the antenna cross section, the gain continues to rise, though at a slower rate. A large horn aperture, corner reflector, or dish can add as much as 3 or 4 dB. Structures of this sort are part surface-wave, part aperture antenna.

The *backfire* antenna, which also combines these two features, produces a gain about 4 dB above that of Eq. 10-15.¹⁶ It consists of a surface-wave line source (for example, a Yagi-Uda, Figure 10-11) terminated by a flat circular plate P , which reflects the surface wave launched by the feed back toward F , where it radiates into space. Its radiation mechanism is not completely understood. The optimum phase velocity is chosen with the aid of the solid curve in Figure 10-9, but ℓ in this context must be reinterpreted as twice the physical antenna length ℓ' of the backfire antenna, since the surface wave traverses the antenna twice. By using Eq. 10-14b, the relation between surface phase velocity and ℓ' (for ℓ' between 1.5λ and 4λ) is $\lambda/\lambda_z = 1 + \lambda/6\ell'$. The feed taper should be much reduced in size or omitted. The plate diameter d is related to ℓ' by

$$\frac{d}{\lambda} \cong 1.5 \sqrt{\frac{\ell'}{\lambda}}$$

which implies that the plate is approximately as large as a paraboloidal dish whose gain equals that of the backfire antenna. For $\ell' = 2\lambda$, the gain is 19 dB, sidelobes are 12 dB down,

FIGURE 10-11 Backfire antenna (after Ehrenspeck¹⁶ 1959)

and bandwidth is at least 20 percent. Easier and cheaper to build than a paraboloidal dish, the backfire antenna might be competitive for gains up to 25 dB (provided sidelobes do not have to be very low); it is superior to ordinary end-fire antennas as long as a low silhouette is not a requirement.

Design for Minimum Beamwidth

The approximate relation between E -plane beamwidth BW_E , H -plane beamwidth BW_H , and gain of a surface-wave antenna is

$$G \cong \frac{30,000}{BW_E BW_H}$$

The half-power beamwidth of a maximum-gain design (Eq. 10-16) can be made 10 percent narrower by increasing the direct-feed radiation, which causes it to interfere destructively with $T(\theta)$ at a smaller angle θ than in Figure 10-7. This is done by starting the feed taper with λ/λ_z less than 1.25. The narrowest beamwidths reported in the literature are plotted in Figure 10-10 as the solid-line margin of the shaded region marked “Beamwidth.” (Usually E -plane patterns are slightly narrower; H -plane patterns, slightly wider.) Sidelobes are about 1 dB higher than in the maximum-gain case.

Design for Minimum Sidelobe Level

The fairly high sidelobes of the maximum-gain design can be reduced by increasing λ/λ_i to 1.35 at the start of the feed taper, letting $\lambda/\lambda_i \cong 1.2$ at the end of the feed taper, and continuing to taper over a large fraction of the total antenna length (to P in Figure 16-6*b*). In the constant cross-section region between P and T , λ/λ_i is chosen to lie on the lower margin of the shaded region in Figure 10-9. If P is two-thirds of the distance from F to T , the sidelobes of a 6λ -long antenna are down at least 18 dB in the H plane and 17 or 21 dB in the E plane of a dielectric rod or Yagi-Uda, respectively, at the cost of a 1.5-dB drop in gain and a 10 percent rise in beamwidth.^{17,18} As in the case of the optimum-gain design, the sidelobe level decreases monotonically with increasing antenna length.

The backlobe is suppressed by increasing the end-fire directivity of the feed pattern. A 25- to 30-dB level can be achieved without resorting to feeds that are much larger than the antenna cross section.

By tapering more sharply near F , then flattening out gradually to a value of λ/λ_z close to 1 at T , the H -plane sidelobe level can be reduced to 20 dB.¹⁸ Gain and beamwidth then lie on the dashed margins of the shaded bands in Figure 10-10. A further reduction to 30 dB in the H -plane sidelobe level is achieved by placing parasitic side rows on either side of the center array¹⁹ (see Figure 10-12). The side-row length ℓ' is slightly longer than 0.5ℓ . λ/λ_z is the same as on the center array (use Eq. 10-14*b*), and the spacing d is optimum when the side rows lie just beyond the 11-dB contour of the surface wave on the center array; or, using Figure 10-3*b* and Eq. 10-14*b*,

FIGURE 10-12 Parasitic side rows for sidelobe suppression in one plane (top view; dots indicate dipoles or monopoles above a ground plane).

$$\frac{d}{\lambda} \cong 0.25 \sqrt{\frac{\ell}{\lambda}}$$

The gain is the same as for maximum-gain design (Eq. 10-15). To reduce sidelobes in all planes, parasitic side rows would have to be placed all around the center array.

Design for Broad Pattern Bandwidth²⁰

The ± 15 percent bandwidth of most surface-wave antennas can be extended to as much as ± 33 percent (2:1) at the cost of a 2-dB gain decrease from optimum at mid-frequency. At the feed, the mid-frequency value of λ/λ_z should be 1.4. A uniform taper extends from the feed to the termination, as shown in Figure 10-1a. At the low-frequency end of the band, gain and beamwidth lie close to the solid margins of the shaded strips in Figure 10-10—at the high-frequency end, close to the dashed margins. Thus gain is constant within ± 1.5 dB and beamwidth within ± 15 percent. On a structure 13.5λ long at mid-frequency, sidelobes were down at least 11 dB throughout the band.²⁰

The bandwidth figures just quoted apply to the polyrod ($\epsilon = 2.56$) and to all surface-wave antennas whose dispersion curve (variation of λ/λ_i with frequency) resembles that of the polyrod. Dispersion increases with increasing dielectric constant; dielectric rods with $\epsilon < 2.56$ are therefore more broadband and rods with $\epsilon > 2.56$ less broadband than polyrods. The dispersion of artificial dielectrics varies; corrugated surfaces are comparable with polyrods, and Yagi-Udas are considerably more dispersive (precise bandwidth figures are not known).

The input impedance of most surface-wave antennas is slightly capacitive and changes slowly with frequency. A tapered dielectric section in waveguide (see Figures 10-1a and 10-6b) provides good matching over a 2:1 bandwidth if 1.5λ long at mid-frequency and over a smaller bandwidth if shorter. To minimize the voltage-standing-wave-ratio (VSWR), an inductive iris is placed close to the insertion point of the rod. Equivalent techniques apply in the case of antennas other than dielectric rods and of input transmission lines other than waveguide.

Feeds

Design principles of feeds and feed tapers for optimum gain, sidelobes, and bandwidth have already been stated. Specific structures will now be described.

In Figure 10-6a, the feeder and reflector monopoles are spaced 0.2λ apart, $h_r = 0.23\lambda$, and $h_f = 0.21\lambda$.¹³ These figures apply to $\delta = 0.048\lambda$; if the elements are thicker, they must be made slightly shorter. The backlobe is between 12 and 15 dB down. By replacing the reflector monopole with a semicircular plate (radius = h_r) or a small corner or paraboloidal reflector (height = h_r), we increase the gain of the feed by at least 1.5 dB and, therefore, the total antenna gain by approximately the same amount. The sidelobes are decreased by at least 2 dB; the backlobe is 25 to 30 dB down.

To couple from the dominant mode in rectangular waveguide, we replace the feeder monopole by a metal half ring²¹ (see Figure 10-13a); the excitation efficiency of this feed, with semicircular reflector plate, is around 80 percent. Another, slightly less efficient but simpler waveguide feed uses two or more slots to couple into the surface-wave structure. The waveguide should be dielectric-loaded so that its phase velocity approximates that in the surface-wave structure, and the slots are spaced about a quarter wavelength apart in the dielectric. Instead of cutting slots, the entire broad face of a dielectric-filled waveguide can be opened (see Figure 10-13b); by tapering the height of the waveguide over the appropriate length, feed and feed taper can be combined in a single design. In low-power applications, striplines can be slot- or dipole-coupled to the antenna.²² In the absence of the ground plane, we use a center-fed dipole (coaxial input with built-in balun, Figure 10-13c) or a folded dipole (usually preferred with two-wire input).

FIGURE 10-13 Surface-wave-antenna feeds: (a) Semicircular wire coupled to waveguide (after DuHamel and Duncan²¹ © IRE 1958); (b) Dielectric-filled waveguide with an open broad wall; (c) Dipole and reflector feed; (d) Circular waveguide cap; (e) and (f) Horn exciters; (g) Parallel-wire (distributed) feed (after Reynolds²⁴ © IRE 1957); (h) Flared transition with lossy strips (with collimating lens shown in horn aperture) (after Stephenson and Walter²⁸ © IRE 1955); (i) Coaxial excitation of disk

The coaxially fed metal cap (see Figure 10-13d), popular as a dielectric-rod feed or a cigar-antenna feed at ultrahigh frequencies (UHF) because of good efficiency combined with mechanical strength, forms the transition between feed types *a* and *b* of Figure 10-6. Type *b* can handle much higher power than type *a*. In Figure 10-6b the waveguide can be rectangular (with TE_{10} mode) or circular (TE_{11} mode). A variant of this form, suitable for Yagi-Uda or cigar-antenna excitation, is shown in Figure 10-13a. If the horn aperture is considerably larger than the antenna cross section (see Figure 10-13f), the surface-wave structure should start well inside, and it is desirable to have the horn extend just beyond the end of the feed taper, as indicated. (Theoretical work shows that for their size, horn apertures are not very efficient surface-wave exciters,²³ but if the direct-feed radiation of the horn is well collimated—the design can be based on Chapter 14—a large total antenna gain will be produced.)

Patterns that closely approximate the $\sin \xi/\xi$ shape have been obtained by flaring a parallel wire into a 60° V (see Figure 10-13g)²⁴ or by running an unflared parallel wire (loaded with transverse wire stubs to reduce phase velocity) alongside the antenna;²⁵ both structures extend over a third of the antenna length. Feeds of this type are called *distributed*. In the hope of obtaining good phase and amplitude control over the entire antenna aperture, feeds have been studied that couple continuously from one end of the antenna to the other, for example, a waveguide slot-coupled to a dielectric slab.^{26,27} These designs have not been very successful thus far, principally because energy flow along two such closely coupled waveguides is difficult to control. If precise aperture illumination is desired, we must abandon surface-wave antennas and turn to the end-fire structures among the surface-wave-excited arrays of discrete elements.

Variants of Figure 10-6a and *b* are also used to excite surface-wave area sources. Rectangular dielectric or corrugated surfaces are fed by placing a slotted waveguide alongside, or a hog horn, or a horn with correcting lens. The last is frequently plagued by transverse standing waves, which produce sidelobes in azimuth (γz plane). To suppress these, a flared transition (1λ long at mid-frequency) with transverse conducting (Aquadag) strips

can be used (see Figure 10-13*h*).²⁸ It keeps sidelobes below 20 dB over a frequency range of at least 2:1 at a cost of 1 or 2 dB because of the lossy strips.

Radial-cylindrical area sources (disks, see Figure 10-2*d*) can be center-fed with a simple monopole feeder; its efficiency of excitation turns out to be higher than with line sources. A higher-gain is shown in Figure 10-13*i*, in which the coaxial input is excited in the TEM mode for vertical polarization on the disk and in the TE_{01} mode for horizontal polarization. A completely flush installation could be achieved by coupling through two or more annular slots. All the arrangements previously described for line sources can be carried over, and the optimum design principles for feed and feed taper still apply.

Arrays of Line Sources

Yagi-Uda, dielectric rods, and other surface-wave line sources can be arranged in a plane or volume array. The surface-wave illumination in the terminal plane of a plane array is scalloped (see Figure 10-14*a*), the overlapping dotted circles representing the 25-dB contours of the transverse-field decay. If identical end-fire elements and negligible interaction between them are assumed, the array gain G_a is the sum of the individual gains G . By letting n be the number of elements and using Eq. 10-15,

$$G_a = nG \cong 10n \frac{\ell}{\lambda} \quad (10-18)$$

Interaction between adjacent elements is found to be negligible if the crossover is at about the 10-dB contour; the minimum separation d is therefore (see Figure 10-3*b* and Eq. 10-14*b*)

$$\frac{d}{\lambda} \cong 0.5 \sqrt{\frac{\ell}{\lambda}} \quad (10-19a)$$

The exact value depends on the polarization (coupling is less in the E than in the H plane) and on the direct coupling between feeds. Too close a spacing produces a loss in gain. An upper limit on the spacing is obtained by requiring that the first principle sidelobe of the array pattern be strongly attenuated through multiplication with the element pattern. The angle with end-fire of the array sidelobe must therefore be at least that of the first minimum in the element pattern, a criterion that corresponds to a crossover of about 22 dB, or a maximum separation

$$\frac{d}{\lambda} \cong \sqrt{\frac{\ell}{\lambda}} \quad (10-19b)$$

FIGURE 10-14 Two-dimensional surface-wave antennas (transverse cross sections): (a) array of line sources and (b) area source

The principle of pattern multiplication, which has just been invoked, is useful only for a first design, since the element patterns are somewhat distorted by the presence of the other elements. The optimum spacing, which lies somewhere between the d/λ values given by Eqs. 10-19, must therefore be found empirically.

The beamwidth BW_a in the plane of the array (azimuth) is approximately

$$BW_a \cong \frac{65\lambda}{nd} \quad (10-20)$$

Sidelobes can be reduced by tapering the amplitude at the feeds. In the elevation plane, beamwidth and sidelobes are controlled by the element pattern. The bandwidth is less than for individual elements, probably about ± 5 percent.

Low-silhouette requirements often force the choice of a horizontal plane array of end-fire elements in place of a vertical cylindrical reflector (or a rectangular mattress array). The trade-off between them, if equal gain and sidelobes and equal width in the y direction (see Figure 10-14a) are assumed, is

$$\frac{\ell}{\lambda} \cong \left(\frac{h}{\lambda}\right)^2 \quad (10-21)$$

(cf. Eq. 10-17), where ℓ is the length of the end-fire elements and h the heights (in the x direction) of the equivalent reflector or broadside array. Because of space limitations, the line sources cannot always be equal in length. Equation 10-18 is then inapplicable, but the spacing between elements is still controlled by Eqs. 10-19.

A volume array of end-fire elements occupies almost as large an area in the transverse (xy) plane as the dish it replaces and has advantages in terms of transportability, ease of erection, and minimum weight needed for mechanical strength against certain kinds of stresses. Spillover is more easily controlled than with a conventional dish, but sidelobe control becomes more difficult and the bandwidth is much narrower. In the design of these arrays, the number of end-fire elements can be reduced by increasing their length; according to Eq. 10-18, $n = G\lambda/10\ell$. This relation clarifies the trade-off between an end-fire volume array and a broadside mattress array of dipoles: though we cannot increase the total gain by replacing the dipoles with higher-gain end-fire elements, we can reduce the number of elements (and thus of separate feeds) while keeping the gain constant.

Arrays of end-fire elements can be fed in cascade from a common transmission line (like slots in waveguide), but a corporate feed structure (branching transmission lines) produces better bandwidth.

Effect of Finite Ground Plane on the Radiation Pattern

Vertically polarized surface-wave line or area sources are often mounted on a ground plane whose finite length g (see Figure 10-15a) distorts the antenna pattern in two ways: by tilting the beam through an angle ψ away from end-fire and by broadening it to a half-power beamwidth BW' . The tilt is maximum when $g = 0$ (no ground plane in front of antenna).^{29,30}

$$\psi_{\max} \cong 60 \frac{\lambda}{\ell} \text{ degrees}$$

(which is a full half-power beamwidth BW of the unperturbed pattern); the beam then broadens so that the 3-dB level lies in the end-fire direction, and BW' is slightly over twice as wide as the unperturbed BW (see Figure 10-15b and c). The tilt can be reduced by slowing the

surface wave down from its infinite-ground-plane optimum, but this increases sidelobes and decreases gain. The gain, on the other hand, is optimized by speeding the wave up at the expense of increased tilt.³⁰

As g increases, the beam tilt decreases: when $g = \ell$, $\psi \cong 0.7\psi_{\max}$; when $g = 3\ell$, $\psi \cong 0.5\psi_{\max}$; when $g = 20\ell$, $\psi \cong 0.2\psi_{\max}$ —a very gradual approach to the infinite-ground-plane condition. The beamwidth approaches the unperturbed value more rapidly: when $g = \ell$, $BW' \cong 1.25BW$.²⁹ Modifying the surface-wave velocity again has an opposite effect on beam tilt and gain.

If no beam tilting or loss in gain can be tolerated, flush mounting must be abandoned in favor of a full-size structure (pod-mounted to reduce drag, if necessary). A less drastic remedy is to reduce the tilt angle, at a small cost in gain, by bending the antenna and ground plane into a cylindrical or spherical cap.^{31–33} The curvature produces an attenuation in the surface wave, which can be enhanced by tapering the antenna along its entire length (see Figure 10-15*d*). If the total attenuation is such that about 50 percent of the power has leaked off before the surface wave reaches the termination, the tilt angle will be reduced to near zero no matter how short the ground plane.³⁰

10.4 SURFACE-WAVE ANTENNAS: SPECIFIC STRUCTURES

Numerical values of λ/λ_z and design details for specific structures are presented in this section. The λ/λ_z curves are displayed for several values of relative dielectric constant ϵ , ranging from 2.56 (polystyrene) to 165 (a calcium titanate ceramic). Hard, low-loss, high-temperature materials, for example, fused quartz ($\epsilon \cong 3.7$), pyroceram ($\epsilon \cong 5.6$), and alite (an aluminum oxide, very durable, $\epsilon \cong 8.25$), are of special interest.

The dielectric-loss tangent δ , which is temperature-dependent, produces a plane-wave attenuation

$$\alpha\lambda = \sqrt{\epsilon} \tan \delta$$

in an infinite medium, but since a large fraction of the surface wave propagates outside the medium, the surface-wave attenuation $\alpha_z\lambda$ is smaller. For $\lambda/\lambda_z = 1.2$, $\alpha_z \cong 0.7\alpha$; for $\lambda/\lambda_z = 1.03$, $\alpha_z \cong 0.1\alpha$.³⁴ As long as δ is smaller than 10^{-2} , the loss will therefore be less than 0.1 dB per wavelength. Data on long Yagi-Uda³⁵ indicate that, for λ/λ_z near 1, loss in artificial dielectrics is likewise negligible, provided all joints are firmly press-fit or soldered and the metal is of high conductivity. As the corrugations or dipole elements approach resonance, λ/λ_z increases and ohmic losses rise sharply. A typical figure for loss in a 6λ -long dielectric rod or Yagi-Uda is 0.5 dB. (Since the maximum-gain curve in Figure 10-10 is based on experiment, the effect of ohmic loss is included.) Surface-wave losses can be measured by the resonator method.³⁶

Because of low frequencies, the metal elements of artificial dielectrics can be constructed of slender poles and chicken wire; they weigh far less than solid dielectrics. Large ground structures at UHF or below are therefore invariably artificial dielectrics. In the microwave range, the choice of medium depends on mechanical strength, temperature behavior, erosion resistance, and cost; ordinary dielectrics, some of which can be cheaply molded into cavities recessed in the skin, are usually preferred for flush airplane or missile installation.

Dielectric Rod^{8,17,20,21,34,37-42}

Dielectric rod is termed *polyrod* and *ferrod* when made of polystyrene and ferrite material respectively. See Figure 10-16a for phase velocity as a function of rod diameter. The higher the dielectric constant, the thinner the rod (for a given gain) and the lighter therefore the weight; however, the larger the dispersion and therefore the narrower the bandwidth.

Modes higher than the fundamental HE_{11} can not propagate provided $d/\lambda < 0.626 / \sqrt{\epsilon}$. The first two higher modes, TE_{01} and TM_{01} , produce a null in the end-fire direction.

Cross sections other than circular are often useful. To a good approximation,³⁴ the phase velocity depends only on the cross-section area A , and Figure 10-16a therefore remains valid if d is replaced by $1.13 \sqrt{A}$. Sliced in half along the plane of electric symmetry (see Figure 10-4c)—which does not affect the phase velocity—a circular or rectangular rod can be placed on a ground plane (*dielectric-image line*, Figure 10-17a and b); when recessed for flush mounting, this structure is called the *dielectric channel guide* (see Figure 10-17c). Another variant, the dielectric tube,⁴² has also been studied but appears to have no advantages over ordinary rods.

Mallach³⁸ found that for optimum design the rod diameter at the feed end of a linearly tapered dielectric rod should be $d_{\max}/\lambda \cong [\pi(\epsilon - 1)]^{-1/2}$, and at the termination $d_{\min}/\lambda \cong [2.5\pi(\epsilon - 1)]^{-1/2}$. In the range $2.5 < \epsilon < 20$, this rule corresponds to letting λ/λ_z at the feed be roughly equal to 1.1 and at the termination to 1.0. The resulting patterns are often adequate but can be improved by using the methods described in Section 10.3.

A rough approximation to the rod pattern, due to Zinke,³⁸ consists in multiplying the $\sin \xi/\xi$ pattern shown in Figure 10-7 by the factor $\cos [(\pi d/\lambda) \sin \theta]$ (but the predicted sharp nulls do not in fact exist).

Figure 10-16b shows details of a conventional feed that has proved itself in practice. Other feeds are illustrated in Figures 10-6 and 10-13. In the case of waveguide feeds, it has

FIGURE 10-16 Dielectric rod: (a) Relative phase velocity (see the literature³⁷⁻³⁹; in case of a noncircular cross section, replace d/λ by $1.13 \sqrt{A}/\lambda$); (b) Conventional feed (after Southworth⁴³ © G. C. Southworth and D. Van Nostrand Company, Inc. 1950)

FIGURE 10-17 Dielectric image lines and channel guide (a) and (b) image lines (identical λ/λ_z if cross section, areas are the same) and (c) channel guide

been found desirable,¹⁷ both for snug fitting and for sidelobe suppression, to wrap dielectric tape around the feed point or, equivalently, to let the diameter of the waveguide feed be slightly smaller than that of the dielectric rod at the feed point, as shown in Figure 10-6b. If $\epsilon > 8$, the rod can be fed over a narrow band by direct insertion in the narrow side of a waveguide, or in a cavity.⁴⁴

Dielectric Channel Guide^{28,45,46} (Figure 10-17c)

Two modes are of interest: a vertically polarized one that is a deformation of the HE_{11} rod mode and a horizontally polarized one. The phase velocity of the vertically polarized mode is very slightly faster in Figure 10-17c than in Figure 10-17a or b. The mode may be slightly leaky (small attenuation in the axial direction), but this is not known with certainty. The structure can be viewed as a channel of the type shown in Figure 10-2b, but with most of the sidewalls removed. The phase velocity is then determined as follows: we rewrite Eq. 10-5b in the form

$$\frac{\lambda}{\lambda_z} = \sqrt{\left(\frac{\lambda}{\lambda_z'}\right)^2 - \left(\frac{\lambda}{2\omega}\right)^2}$$

where λ/λ_z' is the relative phase velocity on an infinitely wide slab-on-metal, as given in Figure 10-19c. Removal of the sidewalls above the dielectric-air interface appears to have negligible effect on the phase velocity²⁸ and, at least as long as $\lambda/\lambda_s > 1$ (ω is not too narrow), introduces little if any leakage attenuation.

The horizontally polarized mode is the lowest-order TE mode in the channel of Figure 10-2b (slightly perturbed by the removal of most of the sidewalls), which in turn is identical with the lowest-order TE mode on a dielectric slab-on-metal (solid curves, see Figure 10-19d).

The dielectric-filled channel also supports leaky waves, and care must be taken not to choose parameters that allow these to be excited.

Yagi-Uda^{13,19,47-62}

These are sometimes referred to as *ladder* arrays. Figure 10-18 shows that the phase velocity is controlled by adjusting the spacing, height, and diameter of the monopole elements.

FIGURE 10-18 Relative phase velocity on Yagi-Uda antenna (after Ehrenspeck and Poehier¹³ © IRE 1959). For the meaning of parameters, see Figure 10-6a.

The dispersion is more pronounced than on a dielectric rod, and the best-reported bandwidth (within which the gain drops no more than 3 dB) is only ± 10 percent; this can perhaps be improved by application of the broadband design method described in Section 10.3. The bandwidth of an array of Yagis is at least ± 5 percent.

The curves in Figure 10-18 apply to the row of monopoles shown in Figure 10-6*a* and equally to a row of dipoles (element height $2h$). A center boom for mounting the dipole elements has negligible effect on the phase velocity provided the total dipole span $2h$ includes the boom diameter. Yagi-Udas can be photoetched on a copper-clad dielectric sheet;^{50,51} since the dielectric slows down the wave, the element height needed to produce a given phase velocity is less than indicated in Figure 10-18.

Dielectric Sheets and Panels^{4,7,31-33,63-68}

Because of the imaging properties of vertically polarized waves, the lowest-order TM mode on a dielectric sheet-on-metal is identical with that on a panel of twice the sheet thickness (see Figure 10-19*a-c*). This wave has no cutoff frequency; its properties are discussed in Section 10.2, and Figure 10-4 shows the field configuration.

The lowest-order horizontally polarized wave on a dielectric sheet-on-metal produces a null in the end-fire direction and has a cutoff (solid curves, Figure 10-19*d*). On a panel, on the other hand, the lowest-order horizontally polarized wave produces a maximum in the end-fire direction and has no cutoff (dashed curves, see Figure 10-19*d*). (The next higher TE mode on the panel is identical with the lowest TE mode on the sheet, but because of the end-fire null it is not a useful mode.)

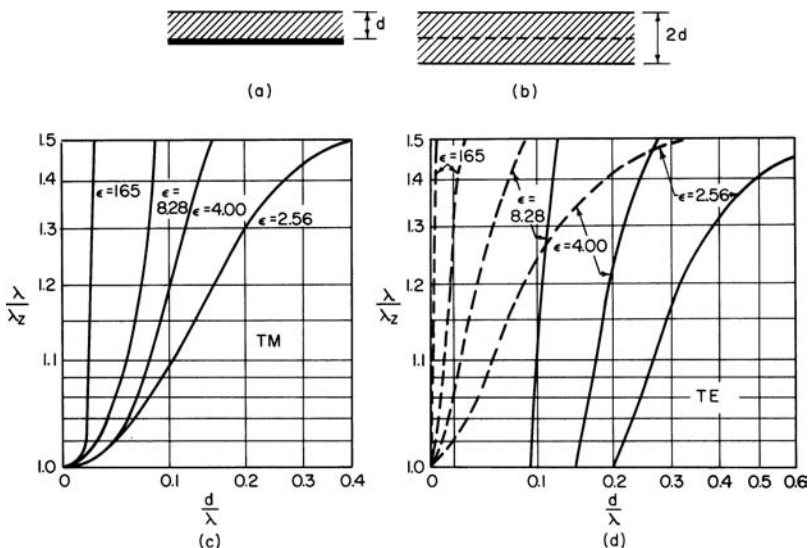

FIGURE 10-19 Dielectric sheets and panels: (a) Sheet-on-metal; (b) Panel; (c) Lowest-order TM mode on sheet or panel; (d) Lowest-order TE mode on sheet (solid curves) and panel (dashed curves)

In designing tapered sheets on metal, a flush air-dielectric interface can be maintained by contouring the depth of ground plane. Good contact between dielectric and ground plane is needed, since air spaces affect the phase velocity.⁷

Circular dielectric disks⁶⁶ and spherical caps^{32,33} are useful as omnidirectional beacon antennas. For design principles, see Section 10.3 (paragraphs on the effect of finite ground plane on the radiation pattern and on beam-shaping techniques). Figure 10-19c and *d* are still applicable, since λ/λ_z is only slightly affected by a decreasing radius of curvature. The leakage attenuation has been calculated by Elliott.³² Patterns provide good null filling to $\pm 45^\circ$ off end-fire and have a bandwidth of ± 8 percent.³³

Circular (or cross) polarization can be produced if the surface-wave structure supports a TM and a TE wave with identical phase velocities. One example is the two-layer dielectric sheet,^{7,67} illustrated in Figure 10-20a for the case in which the lower layer is air. Given λ/λ_z , Figure 10-20b prescribes the layer thickness (with $\epsilon = \epsilon_1/\epsilon_0$ as a parameter). Another, structurally superior, example is the simple-layer dielectric in which longitudinal metal vanes that short out the vertically polarized mode while leaving the horizontally polarized one unperturbed are embedded (see Figure 10-20c). The TM wave therefore “sees” a thinner sheet than the TE wave, and for a prescribed λ/λ_z Figure 10-20b gives the values (in first approximation) of the vane height and total layer thickness. For details, see Hansen.⁶⁸

FIGURE 10-20 Circular (or cross) polarization on dielectric sheets: (a) A simple double-layer structure; (b) Parameter combinations (with $\epsilon = \epsilon_1/\epsilon_0$) that allow (a) to support a circularly polarized surface wave with λ/λ_z between 1.02 and 1.40 (after Plummer and Hansen⁶⁷ © IEE 1957); (c) Longitudinal metal vanes embedded in dielectric (after Hansen⁶⁸ © IRE 1957)

10.5 LONG-WIRE ANTENNAS⁶⁹⁻⁷⁵

Introduction

Long-wire antennas were in active development during the height of the high-frequency era, before 1940, and many different forms evolved. Since then development has been quiescent, the only surviving extant form being the horizontal rhombic antenna. Its continued popularity stems from its simple construction, low cost, and wideband capabilities. The rhombic antenna is uniquely adapted to the propagation of high frequencies via the ionosphere. After 1950, versions of the log periodic antenna have replaced the rhombic for hf communications. (See Chapter 13 for details of log periodic designs.)

The configurations comprising many obsolete long-wire antennas, including the vertical Franklin arrays and the resonant horizontal types, are now history and can be found in the literature.

Some space in this chapter will be devoted to the Beverage antenna, which has desirable applications to the directive reception of low and very low frequencies.

Single Long Wire as a Unit Radiator

Radiation Patterns

The following basic facts about the radiation patterns of long wires isolated in free space with idealized natural current distributions are useful for reference:

1. There is a lobe in the radiation pattern for each half wavelength of wire length. Each lobe is a cone of radiation centered on the wire.
2. With respect to the middle of the wire as center of the polar radiation pattern, half of the lobes are tilted forward and half of them backward. If the wire is an odd number of half wavelengths long, there is an odd number of lobes; so one of them will be normal to the wire.
3. The direction of the electric field reverses in each successive lobe. This is analogous to the reversals of phase of the currents in successive half-wavelength portions of the wire.
4. Between successive lobes are regions of little or no radiation, called nulls or zeros. Practically, these are minima because the field strengths at these angles never actually go to zero. These zeros are related analogously to the current zeros in the standing-wave current distribution or to the phase reversals in a traveling-wave distribution.
5. The angles of the *zeros* are symmetrically distributed about the plane normal to the middle of the wire.
6. For a given electrical length, the angles of the *zeros* are the same for both standing- and traveling-wave current distributions.
7. In the first quadrant the angles of the maxima for both current distributions are virtually coincident. The only exception applies to the direction of the main (first) lobe for wire lengths less than three wavelengths, as may be seen in Figure 10-21.
8. The largest lobe in the radiation pattern is the one forming the smallest angle (θ_1) to the wire. For the traveling-wave case, this lobe is in the direction of current flow only. For the standing-wave case, the radiation pattern is symmetrical with respect to the middle of the wire and so has a complementary major lobe toward the other end of the wire.
9. With a standing-wave current distribution an integral number of half wavelengths long, the envelope of the polar plot of the field-strength distribution pattern is a straight line parallel to the wire or, more correctly, a concentric cylinder. For a nonintegral number of half wavelengths, the middle lobes are further decreased in amplitude. The maximum depression of inner lobes occurs when the current distribution consists of an odd integral number of quarter wavelengths (see Figure 10-22).
10. With traveling waves, the field-strength pattern has lobes of diminishing amplitude, the smallest being in the direction opposite that of current flow.
11. Typical deviations from idealized current distributions modify the relative lobe amplitudes slightly and fill in the zeros slightly but do not affect the *angles* of the maxima or the zeros in the radiation pattern.
12. The ratios of the amplitudes of successive lobes are higher for a traveling-wave system than for the equivalent standing-wave system (compare Figures 10-23 and 10-24).

FIGURE 10-21 Angles of maxima and zeros in the radiation patterns for isolated long wires with natural current distribution

FIGURE 10-22 Comparison between the polar radiation patterns of 7.75λ - and 8λ -long wire with standing-wave current distribution, in terms of relative field strength

FIGURE 10-23 Field-strength radiation patterns for standing-wave current distributions

FIGURE 10-24 Field-strength radiation patterns for traveling-wave current distributions

Comparisons between standing-wave and traveling-wave field-strength patterns can be seen in Figures 10-23 and 10-24.

Horizontal Rhombic Antenna

This antenna is constructed as an elevated diamond with sides from two to many wavelengths long. It is used for transmission and reception of high-frequency waves propagated via the ionosphere. When terminated with a resistance equal to its characteristic impedance at its forward apex, it functions as a traveling-wave antenna; the termination suppresses reflections of transmitted power and absorbs signals from the contrary direction.

Figure 10-25 illustrates optimum electrical parameters and the limits of frequency ratios within which performance is not unreasonably compromised. Note that with less than two wavelengths per leg, the effectiveness of a rhombic antenna is generally regarded as unacceptable because its gain is too low, and in transmission a high percentage of the input power must be dissipated in a terminal resistor. With legs of seven and eight wavelengths, the terminal loss is down to 18 to 24 percent because of the radiation efficiency of such structures.

A resistance-terminated rhombic becomes essentially a transmission line, but this analogy is compromised by the expansion of the line toward the sides and its reconvergence to the forward apex. To improve the uniformity of distributed line constants and to reduce the rhombic's characteristic impedance to convenient values such as $600\ \Omega$, three wires expand from and to each apex on each side. They are at their greatest spread at the sides. The side angles disturb the propagation of currents enough to cause small reflections, but these usually are negligible.

11.1 INTRODUCTION

General Principles

A leaky-wave antenna is basically a waveguiding structure that possesses a mechanism that permits it to leak power all along its length. The earliest example of such an antenna is a rectangular waveguide with a continuous slit cut along its side,^{1,2} as shown in Figure 11-1. Since leakage occurs over the length of the slit in the waveguiding structure, the whole length constitutes the antenna's effective aperture unless the leakage rate is so great that the power has effectively leaked away before reaching the end of the slit. Because of the leakage, the leaky waveguide has a complex propagation wave number, with a phase constant β and a leakage constant α ; α is large or small depending on whether the leakage per unit length is large or small. A large α implies that the large leakage rate produces a short effective aperture, so that the radiated beam has a large beamwidth. Conversely, a low value of α results in a long effective aperture and a narrow beam, provided the physical aperture is sufficiently long.

When the antenna aperture is finite and fixed beforehand and the leakage rate α is small, the beamwidth is determined primarily by the fixed aperture, and the value of α influences the beamwidth only secondarily. What *is* affected strongly by the value of α under those conditions is the efficiency of radiation. We try to design a leaky-wave antenna so that its value of α allows about 90 percent of the power in the guide to be leaked away (radiated) by the time the wave reaches the end of the antenna aperture. The remaining power is absorbed by a matched load placed at the end of the waveguide. A typical leaky-wave antenna might be about 20 wavelengths long, so that the beamwidth of the radiation would be about 4° or so if the beam direction is about 45° from the leaky waveguide axis.

Because the phase constant β changes with frequency, the beam direction also changes with frequency, and the leaky-wave antenna can be *scanned* by varying the *frequency*. The precise ways in which changes in frequency affect the various properties of leaky-wave antennas are considered in detail later.

Since power is radiated continuously along the length, the aperture field of a leaky-wave antenna with strictly uniform geometry has an exponential decay (usually slow). Since the sidelobe behavior is poor for a leaky-wave antenna of typical length, the practice is then to vary the value of α slowly along the length in a specified way while maintaining β constant, so as to adjust the amplitude of the aperture distribution to yield the desired sidelobe performance. This tapering procedure is well known and is discussed later.

FIGURE 11-1 The earliest example of a leaky-wave antenna: a rectangular waveguide with a continuous slit cut along one of its sides

An individual leaky-wave antenna is clearly a line-source antenna. In three dimensions the beam is actually conical in shape, where the detailed beam shape depends on the cross-sectional dimensions of the leaky-wave antenna. Techniques are available for narrowing the beam in the cross-plane, such as the use of a horn or placing the line-source antenna in an array. Examples are given later.

As indicated earlier, the radiated beam of the leaky-wave antenna may be frequency scanned, producing a fan beam narrow in the scan plane. In Section 11.8 we describe how a linear array of such leaky-wave line sources may be used to produce a pencil beam and to permit independent scanning in *two dimensions*. The scanning in the cross-plane requires some mechanism other than a change in frequency, however, and phase scanning seems best. Examples of antennas that scan in two dimensions are presented near the end of this chapter in Section 11.8.

Leaky-wave antennas have been known and used for more than 40 years. Almost all the early antennas were based on closed waveguides that were made leaky by introducing a cut along the side of the waveguide (or something similar to that) to permit the power to leak away along the length of the waveguide. The newer millimeter-wave waveguides are actually *already open*, often in order to reduce the attenuation constants of such waveguides due to metal or dielectric losses. Examples are various kinds of dielectric waveguide, groove guide, NRD guide, microstrip line, etc.; of course, some of these guides are less lossy than others. The dominant modes on these open waveguides are generally purely bound, but a physical cut will not make them leak; instead, some new techniques are necessary, such as the introduction of asymmetry or some other modification of the geometry. Several examples are presented later.

The last remarks in this subsection relate to some confusion in the literature regarding the physics of leaky waves. The limited space available here will permit only a few words of explanation, but an examination of the wave numbers shows that the amplitude of a forward leaky wave *increases* transversely away from the guiding structure so that the wave violates the boundary condition at infinity in the transverse direction. Leaky waves have therefore been called “improper” or “nonspectral.” Although all this is true, these features of leaky waves do *not* complicate the design of leaky-wave antennas; the design principles, which are presented next, are actually quite simple and straightforward. Some simple considerations show that the leaky wave is actually defined only in a sector of space near the leaky-wave antenna and never reaches infinity in the transverse direction because the antenna itself is finite. The leaky-wave concept serves to provide the details of the aperture distribution and some of the main properties of the beam, but the radiation field itself is found in the usual fashion as the Fourier transform of the aperture field. There are some sophisticated mathematical aspects regarding the improper (nonspectral) nature of leaky waves,³⁻⁵ but some of the considerations referred to earlier in this paragraph can be explained in simple geometric terms.²

Two Types of Leaky-Wave Antennas: Uniform and Periodic

There are two different basic types of leaky-wave antennas, depending on whether the geometry of the guiding structure is uniform or is periodically modulated along its length. These two types are actually similar in principle to each other, but their performance properties differ in several ways, and they face somewhat different problems in their design. The two types are therefore treated separately in the discussions that follow.

The *first* type, the *uniform* leaky-wave antenna, is uniform along the length of the guiding structure, as opposed to possessing some periodic modulation. (As mentioned earlier, we recognize that the uniform leaky-wave antenna has a small taper along its length in order to improve and control the sidelobe level.)

All leaky-wave line sources of the uniform type radiate into the forward quadrant and can scan in principle from broadside to end fire, with the beam nearer to end fire at the higher frequencies. In practice, however, you cannot get too close to end fire or to broadside, but how near those limits can be approached depends on the specific structure. For example, suppose the cross section of the guiding structure contains dielectric material in part and air in part, and has a slow-wave range ($\beta > k_0$) and a fast-wave range ($\beta < k_0$), where k_0 is the free-space wave number in air. Then the transition between the two ranges is usually a rapid one, occurring at end fire (when $\beta = k_0$), and the beam can be scanned very close to end fire. An additional virtue of this structure is that a wide scan-angle range can usually be covered with only a relatively small frequency range. An example is given later. When the structure is filled with air only, on the other hand, you must stay about 10 or 15° away from both broadside and end fire, and the frequency sensitivity is more sluggish, particularly near end fire. An important virtue possessed by such single-medium leaky-wave antennas, however, is that the beamwidth remains exactly constant as the beam is scanned with frequency.

In the *second* type of leaky-wave antenna, the *periodic* type, some periodic modulation of the guiding structure is introduced, and it is this periodicity that produces the leakage. The periodic modulation itself is uniform along the structure's length, again except for the small taper of the periodic properties along the length to control the sidelobes. Again, a complex propagation wave number results, with β and α ; large or small values of α are related to the beamwidth and the radiation efficiency in the same manner as that found for uniform leaky-wave antennas. A typical example of a periodic leaky-wave antenna is a dielectric rectangular rod on which a periodic array of metal strips is placed, as seen in Figure 11-2.

An important difference between uniform and periodic leaky-wave antennas is that the dominant mode on the former is a fast wave that therefore radiates whenever the structure is open. On the other hand, the dominant mode on a periodic leaky-wave antenna is a slow wave that does not radiate even though the structure is open. Introduction of the periodic array produces an infinity of space harmonics, some of which may be fast while the rest

FIGURE 11-2 A typical and important example of a periodic leaky-wave antenna: a rectangular dielectric rod (which may or may not be situated on a metal plane) on which is placed a periodic array of metal strips. This antenna can radiate into either the forward or backward quadrants.

are slow; the fast space harmonics would radiate. Since we desire an antenna that radiates only a single beam, the structure is designed so that only the first space harmonic ($n = -1$) is fast. The relevant design considerations are presented in Section 11.3. It is also shown there that the scan range for this class of antennas is from backward end-fire through broadside into part of the forward quadrant, except for a narrow region around broadside, where an “open stop band” occurs.

In general terms, therefore, we see that the scan range is completely different from that for the uniform leaky-wave antennas. There the beam scans in the forward quadrant only; also, it cannot approach broadside too closely, and sometimes it cannot be used too near to end fire. For the periodic leaky-wave antenna, we can scan over almost all the backward quadrant and into some of the forward quadrant as well.

Relation to Surface-Wave Antennas and Slot Arrays

Surface-wave antennas, leaky-wave antennas, and slot arrays are all members of the family of traveling-wave antennas, yet they are treated in this *Handbook* in separate chapters (Chapters 10, 11, and 9, respectively). They are similar to each other in some evident respects (e.g., the basic structure in each case is a waveguide of some sort), but they all differ from each other in important ways that lead to different design procedures and to different performance expectations.

Surface-wave antennas are purely end-fire antennas, whereas leaky-wave antennas and slot arrays do not radiate well in the end-fire direction and, in fact, are designed either to radiate in some other direction or to scan over a range of angles. The basic guiding structure for surface-wave antennas is an open waveguide (such as a dielectric rod) whose dominant mode (the surface wave) is purely bound, so that the surface wave will radiate only at discontinuities, such as the very end of the waveguide. It does not radiate along the length of the guide because the surface wave is a slow wave (except for some small leakage into the almost-end fire direction if the surface-wave antenna is tapered), whereas a uniform leaky-wave antenna, which supports a fast wave, leaks power all along the length of the waveguide.

Periodic leaky-wave antennas, however, are often based on surface waveguides. There the basic waveguide can be an open structure whose dominant mode is a surface wave that is a slow wave, and the radiation is produced by placing a periodic array of discontinuities on the guide in such a way that the first space harmonic becomes fast. The resulting leaky wave may therefore be viewed as arising from a *surface-wave-excited array*. There is thus a strong kinship between the basic structures employed for surface-wave antennas and those for periodic leaky-wave (or surface-wave-excited) arrays, and, for this reason, periodic leaky-wave antennas were, in the first two editions of this *Handbook*, included within the same chapter as surface-wave antennas. On the other hand, since the performance properties of periodic leaky-wave antennas, and the design procedures to achieve those properties, are very different from those for surface-wave antennas but very similar to those for uniform leaky-wave antennas, the leaky-wave antennas of both types are currently incorporated into the present chapter.

The differences between *periodic* leaky-wave antennas and *slot arrays* are more subtle but still very significant. A visually evident difference is that most slot arrays are fed from air-filled rectangular waveguides whose dominant mode is fast; to suppress the radiation from this fast dominant ($n = 0$) space harmonic while retaining that from the $n = -1$ space harmonic, it is necessary to place successive slots on alternate sides of the guide centerline or to alternately tilt the slots to produce phase reversals. Periodic leaky-wave antennas do not need such phase reversals because the (slow) $n = 0$ space harmonic does not radiate. However, this distinction is *not* fundamental, as may be noted when the slot-array rectangular waveguide is dielectric-filled and the alternation of slots is no longer needed. The structures then resemble each other in principle.

The basic distinction between periodic leaky-wave antennas and slot arrays lies in the nature of the individual discontinuities, and, therefore, in the basic design approaches. The intention in the leaky-wave antennas is to produce a slow leakage per unit length; thus each discontinuity element in the periodic array of elements produces a small loading on the basic waveguide mode. The individual elements are intentionally made nonresonant. As a result, the design procedure views the leaky-wave antenna as an equivalent “smooth” structure with a complex propagation wave number, where the array of discontinuity elements is considered as a whole in the analysis.

In contrast, the slots in a slot array are considered *individually*, and then mutual coupling effects are taken into account when the array itself is formed. Furthermore, the individual slots are usually *resonant*. Variations in the loading on the basic waveguide mode are achieved by rotating the slots or by moving them closer to the guide centerline. The design approach thus becomes quite different from that for leaky-wave antennas, thereby warranting inclusion in a separate chapter.

The resonant loading in slot arrays, as opposed to the nonresonant loading in periodic leaky-wave antennas, also influences performance. For example, slot arrays are more frequency-dependent, which can be good if you wish to scan more rapidly with frequency, but the trade-off is that the scan range is narrowed. Most slot arrays are not intended for a large scan range, however. On the other hand, if slot arrays are built with nonresonant slots, their behavior would be very similar to that of periodic leaky-wave antennas. The question then would be whether the customary slot-array design or the leaky-wave design would be more suitable. One last observation relates to the fact that the treatment in Chapter 9 is restricted to slot arrays fed by rectangular waveguide. The design approach described for such arrays could be applied equally well to arrays of other resonant elements, e.g., the two-wire line with proximity-coupled dipoles.⁶

11.2 DESIGN PRINCIPLES FOR UNIFORM LEAKY-WAVE ANTENNAS

The physical structure of a leaky-wave antenna consists of a leaky waveguide with a length L along which the leakage occurs. The propagation characteristics of the leaky mode in the longitudinal (z) direction are given by phase constant β and leakage constant α , where α is a measure of the power leaked (and therefore radiated) per unit length. The length L then forms the aperture of the line-source antenna, and the amplitude and phase of the traveling wave along the aperture are determined by the values of β and α as a function of z . When the leaky waveguide is completely uniform along its length, β and α do not change with z , and the aperture distribution has an exponential amplitude variation and a constant phase. For a leaky-wave antenna of typical length, such an aperture distribution results in a high sidelobe level, so that the design of a practical leaky-wave antenna will include a variation of α with z in order to control the sidelobes in some specified fashion. More is said about this later in this section.

The values of β and α will depend on the precise cross-sectional geometry of the leaky waveguide, and the determination of β and α , whether theoretically or experimentally, is in most cases the most difficult part of the design. Their knowledge, however, is essential to any systematic design procedure.

Once β and α are known as a function of frequency and cross-sectional geometry, the principal behavioral features of a leaky-wave antenna follow very quickly. Such features include the beam direction, the beamwidth, the radiation efficiency, the variation of the scan angle with frequency, and the taper in α required to control the sidelobes.

Beam Direction, Beamwidth, and Radiation Efficiency

These major behavioral features follow directly once the values of β and α are known, and they are given to a good approximation by a set of very simple relations. We first consider the beam direction and the beamwidth:

$$\sin \theta_m \approx \frac{\beta}{k_0} \quad (11-1)$$

$$\Delta\theta \approx \frac{1}{(L/\lambda_0)\cos\theta_m} \quad (11-2)$$

Here θ_m is the angle of the maximum of the beam, measured from the broadside direction (perpendicular to the leaky-wave antenna axis), L is the length of the leaky-wave antenna, $\Delta\theta$ is the beamwidth, and k_0 is the free-space wave number ($= 2\pi/\lambda_0$). Both θ_m and $\Delta\theta$ are in radians in Eqs. 11-1 and 11-2. The beamwidth $\Delta\theta$ is determined primarily by the antenna length L , but it is also influenced by the aperture field amplitude distribution. It is narrowest for a constant aperture field and wider for sharply peaked distributions. Equation 11-2 is a middle-of-the-range result. For a constant aperture distribution, the unity factor in the numerator should be replaced by 0.88; for a leaky-wave structure that is maintained uniform along its length, consistent with 90 percent radiation, the factor should be 0.91; for a tapered distribution that is sharply peaked, the factor could be 1.25 or more (see Table 1-1 for examples).

The antenna length L is usually selected, for a given value of α , so that 90 percent (or at most 95 percent) of the power is radiated, with the remaining 10 percent or so absorbed by a matched load. Attempting to radiate more than 90 percent or so creates two problems: First, the antenna must be made longer, and second, the variation in $\alpha(z)$ required to control the sidelobes becomes extreme. For 90 percent of the power radiated, we find

$$\frac{L}{\lambda_0} \approx \frac{0.18}{\alpha/k_0} \quad (11-3)$$

This simple but useful relation follows from writing

$$\frac{P(L)}{P(0)} = \exp(-2\alpha L) = \exp[-4\pi(\alpha/k_0)(L/\lambda_0)] \quad (11-4)$$

where $P(L)$ is the power remaining in the leaky mode at $z = L$ and $P(0)$ is the power input at $z = 0$.

If both L and α are specified independently, the percentage of power radiated can deviate significantly from the desired 90 percent. In fact, α is a function of frequency, so that the radiation efficiency will change somewhat as the beam is frequency scanned. The 90 percent figure is usually applied to the middle of the scan range. Using Eq. 11-4, however, we can easily obtain an expression for the percentage of power radiated:

$$\begin{aligned} \text{Percentage of power radiated} &= 100[1 - P(L)/P(0)] \\ &= 100\{1 - \exp[-4\pi(\alpha/k_0)(L/\lambda_0)]\} \end{aligned} \quad (11-5)$$

Equation 11-5 assumes an exponentially decaying aperture distribution. If the aperture distribution has been changed in order to control sidelobes, as is customary, Eq. 11-5 is still useful as a good approximation.

Scan-Angle Behavior

There are two different types of uniform leaky-wave antennas that are similar in principle but that differ somewhat in their scan-angle behavior. The guiding structures for these two types differ in that they are *air-filled* for one type and *partially dielectric-filled* for the other.

Typical air-filled guiding structures would include open rectangular waveguide and groove guide, for which the dominant modes are fast relative to the free-space velocity. Guiding structures that are partially dielectric-filled include nonradiative dielectric (NRD) guide and open dielectric-loaded rectangular waveguide. Depending on the frequency and the geometry, the dominant modes on these guiding structures can be fast or slow, but when they are used as leaky-wave antennas, it is necessary to operate them in the fast-wave range ($\beta/k_0 < 1$), of course.

There are advantages and disadvantages in performance when the guiding structures are air-filled or when they are partially loaded with dielectric. With respect to the variation of beamwidth with scan angle, the air-filled structures are superior. Because the transverse wave number is then a constant, independent of frequency, the beamwidth of the radiation remains exactly constant as the beam is scanned by varying the frequency. With partial dielectric loading, on the other hand, the beamwidth changes with scan angle. With respect to frequency sensitivity, i.e., how quickly the beam angle scans as the frequency is varied, the partly dielectric-loaded structure can scan over a larger range of angles for the same frequency change and is therefore preferred.

The reason for these differences in behavior between the air-filled and partly dielectric-loaded cases is shown in Figure 11-3. Let us first recall a few features. We begin with Eq. 11-1, where θ_m is the angle of the maximum of the beam, measured from broadside.

FIGURE 11-3 The variations of the normalized wave number β/k_0 with frequency for uniform leaky-wave antennas that are air-filled or are partly filled with dielectric material. These variations explain their different scan-angle behaviors.

Then we note that the line $\beta/k_0 = 1$ corresponds to end fire, and $\beta/k_0 = 0$ corresponds to broadside. The β/k_0 variation near to cutoff (near to broadside) is seen to be much the same whatever the filling factor of the guiding structure. The big difference occurs near end fire. The variation with frequency for the air-filled case is seen to be quite slow near the $\beta/k_0 = 1$ line because the curve asymptotically approaches that line as the frequency becomes large. For the partly dielectric-filled case, on the other hand, the curve goes quite rapidly to the $\beta/k_0 = 1$ line and above it. As a result, the variation of scan angle with frequency is more rapid overall for the partly dielectric-filled case, and we can approach end fire rather closely in the scan-angle range. In contrast, we cannot approach end fire closely when the guiding structure is air-filled.

We indicated earlier that for air-filled guiding structures the beamwidth $\Delta\theta$ remains constant as the beam is scanned by varying the frequency. This statement is easily proved once we recall that for such air-filled structures the transverse wave number k_c is a constant (k_c independent of frequency). Using Eq. 11-1, we find

$$\cos^2 \theta_m = 1 - \sin^2 \theta_m = 1 - (\beta/k_0)^2$$

Then, since

$$k_0^2 = \beta^2 + k_c^2$$

for air-filled guiding structures, we may write

$$1 - (\beta/k_0)^2 = 1 - [1 - (k_c/k_0)^2] = (k_c/k_0)^2$$

so that

$$\cos \theta_m = k_c/k_0 \quad (11-6)$$

Substituting Eq. 11-6 into Eq. 11-2 yields

$$\Delta\theta \approx \frac{2\pi}{k_c L} = \frac{\lambda_c}{L} \quad \text{in radians} \quad (11-7)$$

which is independent of frequency, provided the antenna is designed according to Eq. 11-3. When the guiding structure is partly filled with dielectric, the transverse wave number k_c is a function of frequency, so that $\Delta\theta$ changes as the beam is frequency scanned.

Radiation Pattern

As usual, the radiation pattern can be found by taking the Fourier transform of the aperture distribution. When the geometry of the leaky-wave antenna is maintained constant along the antenna length, the aperture field distribution consists of a traveling wave with a constant β and α , meaning that the amplitude distribution is exponentially decaying. If the antenna length is infinite, the radiation (power) pattern $R(\theta)$ is given by

$$R(\theta) \sim \frac{\cos^2 \theta}{(\alpha/k_0)^2 + (\beta/k_0 - \sin \theta)^2} \quad (11-8)$$

FIGURE 11-4 Radiation patterns of dielectric grating leaky-wave antennas, showing the changes in the sidelobe behavior with antenna length. These antennas are not tapered to control the sidelobes. (a) Antenna length $L = 10\lambda_0$ (sidelobes clearly present). (b) Antenna length $L = 150\lambda_0$ (no sidelobes) (after Schwering and Peng⁷ © IEEE 1983).

which does not exhibit any sidelobes. If the antenna length is finite, the expression for $R(\theta)$ becomes more involved, and the pattern possesses sidelobes that modify the basic shape for infinite length.

The preceding comments are illustrated well in a paper on dielectric-grating leaky-wave antennas by Schwering and Peng.⁷ They present several examples of such patterns, two of which are shown in Figure 11-4a and b. The length of the antenna in Figure 11-4a, which clearly exhibits sidelobes, is $10\lambda_0$. As the antenna length increases, the amplitude of the sidelobe variations decreases. For the radiation pattern in Figure 11-4b, which shows a smooth pattern only, the antenna length is $150\lambda_0$, which is evidently effectively infinite. Although the leaky-wave antenna for which these calculations were made is periodic rather than uniform, the basic features are identical. Schwering and Peng⁷ contains an extended discussion of radiation-pattern considerations, including equations and other figures.

The radiation pattern in Figure 11-4a is seen to possess first sidelobes that are only about 13 dB down, which is generally undesirable. To greatly reduce the sidelobe level and to control the pattern in other ways, it is customary to appropriately taper the amplitude of the aperture distribution, as is discussed next.

Control of Aperture Distribution to Reduce Sidelobes

The procedure to design the leaky-wave antenna so that it produces a final desired radiation pattern is straightforward, though somewhat complicated, involving the following steps. First, the final desired radiation pattern is specified, and then the corresponding aperture amplitude distribution is determined by standard antenna techniques. Then, by using the expression derived next, the values of α/k_0 are computed as a function of position along the antenna length in accordance with the aperture amplitude distribution that was just determined. At the same time β/k_0 must be maintained constant along the length so that the radiation from all parts of the aperture point in the same direction. Finally, from the theory that relates α and β to the geometry of the structure, we compute the tapered geometry as a function of position along the antenna length.

When we change the local cross-sectional geometry of the guiding structure to modify the value of α at some point z , however, it is likely that the value of β at that point is also modified slightly. However, since β must not be changed, the geometry must be further altered to restore the value of β , thereby changing α somewhat as well. In practice, this difficulty requires a two-step process for most leaky-wave antennas, which is not bad. Because of this added complexity, we seek leaky-wave structures for which we can vary geometric parameters that change β and α essentially independently.

The first design step mentioned earlier, i.e., determining the required aperture amplitude distribution for the selected desired radiation pattern, is a standard antenna procedure not specifically related to leaky-wave antennas. The second step, calculating the value of $\alpha(z)$ corresponding to the aperture amplitude distribution found from the first step, is directly pertinent to leaky-wave antennas, and we therefore present now a derivation of the expression needed for the second step.

The power distribution along the antenna can be expressed in the form

$$P(z) = P(0) \exp \left[-2 \int_0^z \alpha(\zeta) d\zeta \right] \quad (11-9)$$

where $P(0)$ is the power at the input point, $z = 0$, and ζ is the integration variable. Upon differentiation of Eq. 11-9, we obtain

$$-\frac{dP(z)}{dz} = 2\alpha(z)P(z) \quad (11-10)$$

Suppose now that the desired aperture distribution (which would achieve the specified radiation pattern) is $A(z) \exp(-j\beta z)$. We may then write

$$-\frac{dP(z)}{dz} = c |A(z)|^2 \quad (11-11)$$

where c is a constant of proportionality. Comparison of Eqs. 11-10 and 11-11 yields

$$2\alpha(z) = \frac{c |A(z)|^2}{P(z)} \quad (11-12)$$

Upon integration of Eq. 11-11, we obtain, corresponding to two sets of limits of integration, the following:

$$c \int_0^L |A(\zeta)|^2 d\zeta = P(0) - P(L) \quad (11-13)$$

$$c \int_0^z |A(\zeta)|^2 d\zeta = P(0) - P(z) \quad (11-14)$$

We next use Eq. 11-14 to substitute for $P(z)$ in Eq. 11-12, and then we employ Eq. 11-13 to eliminate the proportionality constant c . In a straightforward fashion, we then obtain the desired result:

$$2\alpha(z) = \frac{|A(z)|^2}{\frac{P(0)}{P(0) - P(L)} \int_0^L |A(\zeta)|^2 d\zeta - \int_0^z |A(\zeta)|^2 d\zeta} \quad (11-15)$$

The units of $\alpha(z)$ in Eq. 11-15 are nepers per unit length. To obtain $\alpha(z)$ in decibels per unit length, we multiply by 8.68. If $P(L)$, the power remaining at the end of the aperture, is allowed to approach zero, we note from Eq. 11-15 that $\alpha(z)$ then becomes very large for points near to the end of the aperture, i.e., for z approaching L . This is the main reason why it is common for $P(L)/P(0)$ to be equal to 0.1 or so, but not much smaller, with the remaining power being absorbed in a matched load to avoid the presence of any backlobe.

11.3 DESIGN PRINCIPLES FOR PERIODIC LEAKY-WAVE ANTENNAS

As discussed in Section 11.1, periodic leaky-wave antennas differ from uniform ones in that the waveguiding structure is modulated periodically along its length instead of being completely uniform (again, except for the small taper for both types to control the side-lobes). The dominant mode on uniform antennas is fast relative to free-space velocity, whereas the one on periodic antennas is slow, so that the dominant mode itself does not radiate and it needs the periodic modulation to produce the radiation. Since the physical processes that produce the radiation are different, these two antenna types have different scan ranges. On the other hand, most of the design principles for the uniform leaky-wave antennas discussed in Section 11.2 also apply to the periodic ones. The treatment given next indicates in what ways changes in design are necessary. First, however, we summarize how the periodicity produces the leakage and, in that context, why the scan ranges are different for the two types.

Effect of Periodicity on Scan Behavior

To explain the source of the leakage and to understand the scan behavior as a function of frequency, we invoke the concept of *space harmonics*. Suppose we first take a uniform dielectric waveguide, and then we place an array of metal strips periodically along its length (as in Figure 11-2). Before the metal strips are added, we choose the guide dimensions and frequency so that only the dominant mode is above cutoff; furthermore, $\beta > k_0$ for this mode, so it is purely bound. When the periodic array of strips is added, the periodicity

introduces an infinity of space harmonics, each characterized by phase constant β_n and related to each other by

$$\beta_n d = \beta_0 d + 2n\pi \quad (11-16)$$

where d is the period and β_0 , the fundamental space harmonic, is simply the original β of the dominant mode of the uniform dielectric waveguide, but perturbed somewhat in value because of the addition of the strips. As seen from Eq. 11-16, β_n can take on a large variety of values, so that these space harmonics can be forward or backward in nature, and be slow or fast. Since the structure is open, a space harmonic that is fast will radiate. To say it in another way, since the space harmonics are all tied together, and all of them together comprise the dominant mode of the loaded structure, the whole mode becomes leaky if one or more of the space harmonics becomes fast.

We recall that for a space harmonic to be fast, we need $\beta_n/k_0 < 1$; we also know that $\beta_0/k_0 > 1$. If we rewrite Eq. 11-16 in the form

$$\frac{\beta_n}{k_0} = \frac{\beta_0}{k_0} + \frac{2n\pi}{k_0 d} = \frac{\beta_0}{k_0} + \frac{n\lambda_0}{d} \quad (11-17)$$

we see that $|\beta_n/k_0|$ can readily be less than unity if n is negative and λ_0/d is suitably chosen. For a practical antenna, we want only a single radiated beam, so we choose $n = -1$.

If we follow this line of thinking further (the details will not be given here), we will find that when the frequency is low, all the space harmonics are slow and there are no radiated beams. When the frequency reaches the critical value for which the $n = -1$ space harmonic first becomes fast, the radiating beam just emerges from backward end-fire. As the frequency is increased, the beam swings up from backward end-fire but is still radiating into the backward quadrant. Further increases in the frequency will swing the beam toward broadside, then through broadside, and finally into the forward quadrant. The amount by which the forward quadrant is penetrated depends on other properties of the antenna, in this case primarily on the dielectric constant. On the other hand, the antenna is useful only if a single, controllable beam is radiated, and the range in the forward quadrant is usually limited by the emergence of the $n = -2$ beam from backward end-fire, or by the next waveguide mode coming above cutoff.

A special problem is present for the periodic structures near broadside. A narrow region around broadside corresponds to an "open stopband" region, where the value of α becomes large and then zero (for a structure of infinite length). In a practical antenna, this means that within this narrow angular region the amount of radiation drops substantially, and a large VSWR is encountered (power is reflected back to the source rather than being radiated). This effect is well known, and it also occurs when slot arrays are scanned through broadside. There are techniques, not widely used, that permit these arrays to scan through broadside, however. One of them^{8,9} uses pairs of strips rather than single strips, where the spacing between the elements of each pair is $\lambda_{g0}/4$ (where λ_{g0} is the guide wavelength) at the broadside frequency, so that the wave reflected at broadside by the first element of each pair will be canceled, or nearly so, by the wave reflected by the second element.

Beam Direction, Beamwidth, and Radiation Efficiency

The discussion in Section 11.2 under this heading shows that these major behavioral features are given to a good approximation by a set of very simple relations. All the considerations

presented there for uniform leaky-wave antennas apply as well to periodic leaky-wave antennas provided that we make one simple change, which takes into account the main difference between the two antenna types. The main difference relates to the fact that radiation from *periodic* leaky-wave antennas is due to the $n = -1$ space harmonic. In Eq. 11-1, therefore, β must be replaced by β_{-1} , to yield

$$\sin \theta_m \approx \frac{\beta_{-1}}{k_0} \quad (11-18)$$

where

$$\beta_{-1} = \beta_0 - 2\pi/d \quad (11-19)$$

consistent with Eq. 11-16. When we substitute Eq. 11-19 into Eq. 11-18, we obtain

$$\sin \theta_m \approx \frac{\beta_0}{k_0} - \frac{2\pi}{k_0 d} = \frac{\lambda_0}{\lambda_{g0}} - \frac{\lambda_0}{d} \quad (11-20)$$

Thus, depending on how λ_0/d , where d is the period, compares with λ_0/λ_{g0} (or β_0/k_0), the beam can point in the backward quadrant or in the forward quadrant, in accordance with the discussion in the preceding subsection.

Equations 11-2 through 11-6, and the discussions relating to them, also apply to periodic leaky-wave antennas when the distinction relating to β_{-1} is kept in mind.

The considerations in Section 11.2 relating to the radiation pattern, as well as to the steps required to control the aperture distribution, are also valid here.

Feed Considerations

When the antenna aperture is tapered appropriately in accordance with the design steps outlined in Section 11.2 in the subsection “Control of Aperture Distribution to Reduce Sidelobes,” very beautiful radiation patterns, with very low sidelobes, can be achieved on paper. These fine results can also be obtained in practice when proper attention is also paid to the way the leaky-wave antennas are fed.

For uniform leaky-wave antennas that are formed by opening up initially closed waveguides, concerns relating to the feed are usually negligible or nonexistent. The reason for this lies in the taper process for controlling the sidelobes. The taper is such that the aperture radiates very little at its ends, and therefore the discontinuity between the closed feed waveguide and the antenna aperture when it first begins is extremely small in most cases. There is therefore negligible spurious radiation from the feed junction. There is also no appreciable impedance mismatch at that feed junction, of course.

When the feeding structure is an open waveguide, we must examine the situation more carefully. This is particularly true for those periodic leaky-wave antennas that are basically surface-wave-excited. The problem then lies with the way the basic surface wave is produced, rather than with the transition to the periodic modulation, which again begins very slowly due to the taper. Surface waves are often formed by a tapered transition from a closed waveguide, with resultant spurious radiation associated with the transition. Such problems are well known with respect to surface-wave antennas. When such transitions form part of the overall feed system, their contributions to the radiation pattern may be significant and may spoil the initial careful paper design.

In many cases, spurious feed radiation is not a problem with leaky-wave antennas, and this is one of their important virtues, but the feed mechanism must be looked at

carefully in the design to make sure that it does not introduce its own contribution to the radiation pattern.

11.4 SPECIFIC STRUCTURES: OVERVIEW

Leaky-wave antennas are formed by perturbing an initially bound mode on a waveguiding structure in a way that produces leakage all along the length of the guiding structure. As might be expected, all the very early leaky-wave antennas were based on *closed waveguides*, and the leakage was achieved by physically cutting into a wall of the waveguide, in the form of a longitudinal slit or a series of closely spaced holes. The first known leaky-wave antenna, shown in Figure 11-1 and invented by W. W. Hansen¹ in 1940, was in fact a long slot in a rectangular waveguide.

The next section presents several of the more important leaky-wave antennas based on *closed* waveguides. These structures are usually very simple in cross section, so that it was possible to obtain accurate expressions for the complex wave number ($\beta - j\alpha$) in terms of the frequency and the geometry of the cross section. Since very little spurious radiation occurs because of the feed junction, the theoretically derived radiation patterns, based on designs that yielded low sidelobes, agreed extremely well with the measured radiation patterns. A dramatic example of excellent agreement is given in Section 11.5. Many of the early theoretical expressions and the design based on them are still of practical value today and are indeed so good that the initial designs were often the final ones, without the need for any empirical adjustments.

The data relating the wave-number behavior to the geometric parameters are usually plotted as β/k_0 or $\lambda_0\lambda_g$, where λ_g is the guide wavelength in the propagation direction (z), and as α/k_0 or $\alpha\lambda_0$, where α is the leakage constant. In previous editions of this *Handbook*, plots were presented in the form of λ/λ_z and $\alpha_z\lambda$, where α_z , λ , and λ_z were written instead of α , λ_0 , and λ_g . Where the discussion and graphical plots in the present chapter employ material taken from the previous edition, the previous notation is carried over. It is essential that such information be available for any specific antenna structure because the correct taper for low sidelobes cannot be designed without it. A last general remark to be made in connection with leaky-wave structures based on closed waveguides is that some of the structures employ a series of round holes or small (nonresonant) slots. These holes or slots, however, are closely spaced, so that the structures should be viewed as quasi-uniform rather than periodic, even though these holes are periodically spaced. The radiation produced by them radiates the $n = 0$ space harmonic and not the $n = -1$ space harmonic.

The next stage in the development of specific leaky-wave antennas involved those based on *open* waveguides. Some of these antennas are uniform structures that employ open waveguides on which the dominant mode is initially purely bound, and others are periodic structures that are excited by surface waves and radiate via the $n = -1$ space harmonic. These two categories are considered separately in Sections 11.7 and 11.6, respectively.

The best-known examples of surface-wave-excited *periodic* leaky-wave antennas are dielectric rectangular rods (or slabs), with or without ground planes, that have on their tops or on one of their sides a periodic array of grooves or a periodic array of metal strips. Another large group is based on microstrip line. These antennas have been studied rather extensively, both experimentally and, more recently, theoretically. Together with other, similar structures, they are discussed in Section 11.6. An important problem for this class of structures is the incorporation of a feed mechanism that does not contribute spurious radiation.

Uniform leaky-wave antennas based on *open* waveguides offer a special challenge. Since the guide is already open, it cannot be cut to induce radiation, and other approaches

are needed. The most common one is the appropriate introduction of asymmetry, but other mechanisms, such as the use of a leaky higher-order mode or some modification in the geometry, have also been found useful. The first (and only early) example of such a leaky-wave antenna based on an open waveguide was invented by W. Rotman in the late 1950s. This pioneering study^{10,11} involved several versions of a form of trough waveguide whose dominant mode is purely bound but was made leaky by introducing asymmetry. The design procedure for this antenna was successful and practical, but the approach was not pursued further until about 20 years later, in the context of a new need that emerged in connection with millimeter waves.

As interest in millimeter waves revived during the 1970s, it was recognized that new forms of leaky-wave antennas were needed because of the smaller wavelengths involved and because the usual waveguides had higher loss at those higher frequencies. Since these smaller wavelengths caused fabrication problems due to small dimensions, simpler structures were sought; in fact, the latest structures are designed to permit the complicated portion of the structure, including the taper for sidelobe control, to be deposited photolithographically, in printed-circuit form, by using a mask. Because of the loss considerations, the newer antennas are often based on new lower-loss waveguides designed for millimeter-wave applications.

These include nonradiative dielectric (NRD) guide, groove guide, and rectangular dielectric rods, sometimes used in conjunction with microstrip in novel ways. Unfortunately, these last-mentioned structures were difficult to analyze theoretically, so their designs were empirical only; as a result, the experimental radiation patterns showed poor sidelobe performance, leading some people to conclude unfairly that poor sidelobe behavior was a necessary consequence of this class of antennas. However, many other leaky-wave antennas in this class were analyzed accurately, primarily by Oliner and his colleagues, and their results agreed very well with measurements. Some of the more promising of these newer millimeter-wave antennas are described in Section 11.7.

A more recent development relating to leaky-wave antennas is their incorporation into arrays that permit scanning in two dimensions. The arrays are essentially a linear phased array of leaky-wave line-source antennas, where the scanning in elevation is obtained in leaky-wave fashion by varying the frequency, and the scanning in azimuth is achieved by varying the phase difference between the successive parallel leaky-wave line sources. The architecture underlying this approach is described in Section 11.8, and several examples are given of specific antenna structures in this category. A partial motivation for this approach is to achieve a lower-cost substitute for phased-array antennas in some applications.

11.5 SPECIFIC STRUCTURES BASED ON CLOSED WAVEGUIDES

The earliest example of a leaky-wave antenna was the one for which W. W. Hansen was granted a patent.¹ He had proposed during the late 1930s that an antenna could be created by cutting a rectangular waveguide longitudinally, as shown in Figure 11-1, thereby producing a long slit in the side of the initially closed guide, out of which power could leak away. His concept was not pursued at that time because of the success of slot arrays, but the simplicity of the structure remained attractive, and it was reexamined about a decade later. The 1950s, in fact, represented a very active period during which many leaky-wave antennas based on closed waveguides were proposed, analyzed, measured, and utilized. Several excellent references summarize in detail the state of the art in this class of antennas as of the middle 1960s, including a comprehensive book¹² by C. H. Walter; a chapter by F. J. Zucker¹³ in the First Edition of this *Handbook*; a chapter by T. Tamir¹⁴ in Part II of

the book *Antenna Theory*, edited by R. E. Collin and F. J. Zucker; and a summary by A. A. Oliner and R. G. Malech¹⁵ in Volume II of the book *Microwave Scanning Antennas*, edited by R. C. Hansen.

All these specific structures based on closed waveguides are “uniform” leaky-wave antennas, so the principles for their design are those discussed earlier in Section 11.2. The remaining information required to complete the design involves the expressions for β/k_0 ($=\lambda/\lambda_z$) and α/k_0 (or $\alpha_z\lambda$) as a function of the frequency and geometric parameters of the specific structure. Since the period before the middle 1960s predates the computer era, theoretical expressions had to be simple to be considered practical. Fortunately, the structures themselves were simple, leading automatically to relatively simple expressions that were accurate, but, in addition, many of the expressions were further simplified by the use of perturbation relations.

In some cases, these values of α and β were measured rather than calculated, and then employed in the design. Two experimental methods are outlined in Walter’s book.¹⁶

Long Slits in Rectangular Waveguide

Radiation from long slits in rectangular waveguide can be accomplished in several ways, where the leakage rate can be adjusted by changing the slit width, and the polarization of the radiated beam can be selected by changing the waveguide mode. Some examples are illustrated in Figure 11-5.

The best-known example in this well-known category is the narrow slit in the side wall of rectangular waveguide shown in Figure 11-1, or the same structure with a ground plane seen in Figure 11-5a. The antenna shown in Figure 11-5a also differs from the structure in Figure 11-1 in that it is rotated by 90° and the slit is shown tapered (in exaggerated fashion) to remind us that in the design the slit width is varied to control the sidelobes in the radiation pattern. (The rectangular waveguide dimensions h and w correspond, of course, to the usual a and b , respectively.)

For this antenna, with the ground plane present but with the slit uniform, simple theoretical expressions are available for the relations between λ/λ_z and $\alpha_z\lambda$ and the frequency and the geometry. These expressions were derived by Goldstone and Oliner¹⁷ using a transverse resonance approach together with a simple perturbation procedure. The results agreed very well with measurements. The expressions (with the notation differing somewhat from that in Goldstone and Oliner¹⁷ to be consistent with Figure 11-5a) are

$$\frac{\lambda}{\lambda_z} = \frac{\lambda}{\lambda_{z0}} \left(1 - \frac{\lambda_{z0}^2}{2\pi^2 hw} \frac{p}{1+p^2} \right) \quad (11-21)$$

and

$$\alpha_z\lambda = \frac{\lambda\lambda_{z0}}{\pi hw} \frac{1}{1+p^2} \quad (11-22)$$

where

$$p = \frac{2}{\pi} \left[\ln \left(\csc \frac{\pi\delta}{2w} \right) + \ln \left(1.526 \frac{h}{\delta} \right) \right] \quad (11-23)$$

and λ_{z0} is the guide wavelength, that is,

$$\lambda_{z0} = \lambda / \sqrt{1 - (\lambda/2h)^2} \quad (11-24)$$

in the unperturbed waveguide ($\delta = 0$). Zero ground-plane thickness is assumed. Although λ/λ_c and $\alpha_c\lambda$ are not strictly separable, λ/λ_c is controlled primarily by variations in h (through λ_{c0}) and $\alpha_c\lambda$ by variations in δ . For operation at frequencies near cutoff, you should use the exact solution (also in Goldstone and Oliner¹⁷) instead of the perturbation form given here.

FIGURE 11-5 Several examples of leaky-wave antennas based on long slits in rectangular waveguide. (a) Narrow slit in the narrow wall, shown with an exaggerated taper. The remaining figures show the relative guide wavelength λ/λ_z and the relative leakage constant $\alpha_z\lambda$ for (b) the channel-guide antenna, (c) the dielectric-filled channel, for $\epsilon_r = 2.56$, and (d) a narrow slit in square guide. The dominant mode excites the slit in the first three cases, while the TM_{11} mode excites the slit in the last case (after Goldstone and Oliner¹⁷ © IRE (now IEEE) 1959 and Hines et al¹⁸ © IRE 1953).

When the rectangular waveguide is dielectric-filled, Eqs. 11-21 to 11-24 must be modified appropriately; such expressions are given in Walter,¹² on pages 189 and 190.

Although expressions corresponding to Eqs. 11-21 through 11-24 are also available in Goldstone and Oliner¹⁷ for the structures in Figure 11-5*b* and *d*, and in Walter¹² for that in Figure 11-5*c*, results for these structures are displayed graphically in Figure 11-5 to illustrate how the numerical values for normalized β and α vary with frequency. Theoretical expressions for these long slit structures have also been derived by Rumsey¹⁹ and by Hines et al¹⁸ using a variational approach. Modifications of the theoretical expressions given in Goldstone and Oliner¹⁷ for these structures when dielectric loading is present are contained in Chapter 5 of Walter.¹²

It should be recognized that the slit fields in the structures in Figure 11-5 *a*, *b*, and *c* have $E_z = 0$, and that the transverse electric field in the aperture is equivalent to a longitudinal (z -directed) magnetic current. The resulting radiation pattern is horizontally polarized. In contrast, the slit in the structure in Figure 11-5*d* has $H_z = 0$ and primarily constitutes a longitudinal electric current, so that the antenna radiates with vertical polarization.

The configurations in Figure 11-5*b* and *c*, for which the slit has been opened up to the full guide width (w), are generally referred to as *channel-guide antennas*.^{20,21} Because the slit is so wide, however, the leakage constant can become large rather easily. Even in the structure in Figure 11-5*a*, however, the slit cuts directly across the electric field lines, corresponding to the logarithmic dependence seen in Eq. 11-23, so that the leakage rate will never be very small. If a leaky-wave antenna with a very narrow beam is required, therefore, you need to go to a structure like that containing the series of closely spaced holes described later in this section.

Measurements have been taken on all these structures, and the agreement with theory has been excellent. However, most of these measurements have been on untapered slits. Measurements on tapered-slit antennas have been reported, e.g., in Hines et al¹⁸ and Rotman.²¹ For the antenna in Figure 11-5*a*, good control over the sidelobes has been achieved,¹⁸ a typical result being that a Gaussian amplitude distribution produces low sidelobes over an almost 2:1 frequency range in which the beam swings from 38 to 18° off end fire.

Many years later, a modified long-slot structure was proposed and analyzed²² that provides radiation patterns with very low sidelobes within a relatively short length and with high efficiency. The long slot is located on the top wall of rectangular waveguide, and it moves from the centerline of the top wall out to near the side wall and back to the centerline in a very strong, but specified, curved fashion. The designers call this variation their *meander* contour. Numerical results were provided, though no experimental verification was given.

Long Slits in Circular Waveguide

The radiation properties of leaky-wave antennas based on long slits in circular waveguide are qualitatively similar to those for long slits in rectangular waveguide, as discussed earlier. Three independent theoretical analyses appear to be available. The first two, by Harrington²³ and by Rumsey,¹⁹ employ a variational approach, and the authors present accurate results that agree very well with their independently obtained measurements. The third analysis, by Goldstone and Oliner,²⁴ uses a transverse resonance approach in the radial direction and develops expressions for the slit using radial transmission-line theory. The authors obtain explicit expressions for the phase and leakage constants in a relatively simple, explicit form, in contrast to the other two theories, and these expressions are also much simpler to compute from. The results also agreed well with Harrington's measurements.²³

FIGURE 11-6 Long slits in circular waveguide: (a) TE_{10} mode excitation; (b) TM_{01} mode excitation (after Harrington²³ and Goldstone and Oliner²⁴ © IRE (now IEEE) 1961)

Numerical results for air-filled circular waveguides supporting the TE_{11} mode and the TM_{01} mode, to furnish opposite types of polarization, are presented in Figure 11-6a and b, respectively. Explicit expressions for air-filled guides are given in Goldstone and Oliner,²⁴ and the modifications in those expressions for the dielectric-filled case are included in Chapter 5 of Walter.¹²

Closely Spaced Holes in Rectangular Waveguide

A problem relating to the structures in Figure 11-5a–c is that the opening directly disrupts the current lines, so you cannot, with such a geometry, obtain a very narrow radiated beam. A way to surmount this difficulty is to replace the long slit (or the channel-guide geometry) with a series of closely spaced small holes, as shown in Figure 11-7. Then the current lines are simply pushed aside by the holes, and they can go around them. Since the holes perturb the initially closed guide much less than the long slit does, the resulting value of α is much smaller. Finally, since the holes are closely spaced, the structure is quasi-uniform and the design principles in Section 11.2 apply.

The antenna employing a series of closely spaced round holes was proposed and measured at the Ohio State University,²⁵ and it became known as the OSU “holey guide.” By varying the diameter d of the holes and, to a lesser extent, the hole spacing s and the guide width w , a very large range in the value of $\alpha\lambda_z$ was found experimentally. This structure was also analyzed by Goldstone and Oliner,¹⁷ by employing small aperture procedures for the series of holes, together with a transverse resonance approach. Using a perturbation form for the

FIGURE 11-7 Quasi-uniform aperture in rectangular waveguide to permit narrow radiated beams; closely spaced round holes in the narrow wall (“holey guide”) (after Hines and Upson²⁵)

result, they obtained the following simple expressions (using the notation in Eqs. 11-21 and 11-22):

$$\frac{\lambda}{\lambda_z} = \frac{\lambda}{\lambda_{z0}} \left[1 + \frac{\lambda_{z0}^2}{4\pi h^2} X' \right] \quad (11-25)$$

and

$$\alpha_z \lambda = \frac{\lambda \lambda_{z0} R'}{2h^2} \quad (11-26)$$

where

$$X' = \frac{B'}{(G')^2 + (B')^2} \quad R' = \frac{G'}{(G')^2 + (B')^2} \quad (11-27)$$

$$G' = \pi w/2h \quad (11-28)$$

$$B' = 6hws/\pi d^3 \quad (11-29)$$

$$\lambda_{z0} = \lambda / \sqrt{1 - (\lambda/2h)^2} \quad (11-30)$$

Calculations from these expressions agreed very well with measurements made both at the Ohio State University (Walter,¹² Chapter 5) and the Polytechnic Institute of Brooklyn.¹⁷ When the frequency of operation is near to cutoff, these perturbation expressions become inaccurate, and we should instead solve the transverse resonance relation¹⁷ exactly.

Array of Closely Spaced Wide Transverse Strips

This array of transverse strips, sometimes called an *inductive-grid antenna* and due to R. C. Honey,²⁶ is shown in Figure 11-8a. The antenna consists of a parallel-plate waveguide operated in its first higher-order (TE₁) mode, with its upper plate composed of an array of closely spaced transverse strips, and fed from a reflector arrangement so as to fill the space with the field having the polarization shown in Figure 11-8a. The upper plate can be photoetched on a thin laminate and then be supported by polyfoam, or it can consist of a grid of transverse round wires.

The structure was analyzed²⁶ by using the transverse resonance method, which yielded simple and accurate expressions for the λ/λ_z and $\alpha_z \lambda$ values. From these expressions we can compute the design curves presented in Figure 11-8b and c. The design procedure is to first select the desired λ/λ_z and $\alpha_z \lambda$ and then to read from the curves in Figure 11-8b the corresponding abscissa value. The curves in Figure 11-8c then yield the value of d for the design wavelength corresponding to the abscissa value obtained from Figure 11-8b. Now, in a design for low sidelobes in some specified fashion (see Section 11.2), $\alpha_z \lambda$ must vary from point to point in a tapered fashion along the longitudinal direction, while λ/λ_z must remain the same at each point. The plot in Figure 11-8b then tells us how c can be varied, by changing the strip width t , to obtain the desired different values of $\alpha_z \lambda$ while trying

FIGURE 11-8 Inductive-grid antenna comprised of a parallel-plate guide fed in its first higher-order TE mode and with its upper plate consisting of a series of closely spaced wide transverse strips: (a) structure; (b) relative leakage constant with the normalized guide wavelength as a parameter; (c) a plot to aid in the design procedure (see text). Quantity c , which appears in the abscissas of parts (b) and (c), is defined as $c = 2\pi d/p \ln [\csc (\pi/2p)]$ (after Honey²⁶ © IRE (now IEEE) 1959).

to maintain λ/λ_z constant. However, λ/λ_z will change somewhat as t is varied, since it is not independent of t , and the plot in Figure 11-8c then indicates how d can be modified to change λ/λ_z back to the desired constant value.

In his final design, Honey²⁶ found that it was necessary to flex the bottom plate slightly along the longitudinal direction, and he built his structure accordingly. He was also meticulous with respect to both the accuracy of his theory and the details of the structure to be measured. As a result, the correspondence between his theoretical and measured radiation patterns was *remarkably good*, down to almost -40 dB, as may be observed in Figure 11-9.

11.6 SPECIFIC STRUCTURES BASED ON PERIODIC OPEN WAVEGUIDES

The design principles for leaky-wave antennas based on periodic open waveguides are presented in Section 11.3. The important points to recall are that the basic open waveguide supports a slow wave, which does not radiate, and that the period of the structural modulation is selected relative to the wavelength so that the $n = -1$ space harmonic, and only that

FIGURE 11-9 Theoretical (a) and measured (b) radiation patterns for the inductive-grid antenna shown in Figure 11-8a. The accurate theoretical design and the carefully fabricated experimental structure both took into account the taper for low sidelobes. The agreement between the two patterns is seen to be remarkable (after Honey²⁶ © IRE (now IEEE) 1959).

one, radiates the power. In contrast, the periodic structures discussed in Section 11.5, such as the closely spaced series of round holes in rectangular waveguide, are based on a fast wave and are quasi-uniform so that only the $n = 0$ space harmonic radiates. Furthermore, the beam radiated from the periodically modulated slow-wave structures may be scanned throughout most of the backward quadrant and into part of the forward quadrant, whereas the beam radiated from the uniform or quasi-uniform structures is restricted to the forward quadrant only.

The two most common open waveguides that support dominant modes and which serve as the basis for periodic leaky-wave antennas are rectangular dielectric rods, with or without ground plane, and microstrip line. The class of dielectric rods includes a variety of known waveguides, such as dielectric image guide, insular guide, inset guide, and so on. Since the leaky wave is fast and the basic surface wave (or microstrip dominant mode) is slow, we must be careful about the feed arrangement to make sure that little spurious radiation is introduced.

Many of these periodic leaky-wave antennas have been known (measured and used) for some years, but accurate theories for β and α , suitable for careful design purposes, have become available only recently, and only for some structures.

Early Structures

A few pioneering examples in this class were proposed and studied as far back as the late 1950s, but the ideas behind them were not pursued then. When they did reemerge, a decade or two later and in a somewhat different form, most people did not recognize the relationship with the past. Two examples of this early novel thinking are presented here.

The first structure is based on the original dielectric image guide, due to D. D. King,²⁷ which consists of the top half of a round dielectric rod placed on a ground plane.

The fields of the dominant mode on the rod (the TE_{11} mode) extended substantially into the air region transversely, as did the current lines on the ground plane. In the leaky-wave antenna configuration²⁸ based on this guide, a two-dimensional (2D) array of slots was cut into the ground plane on each side of the rod. In this way the (loosely bound) surface wave guided by the rod excites each *row* of slots in phase, with an illumination corresponding to the transverse decay rate of the field, and each *column* of slots in accordance with the propagation wave number β . Depending on the type, orientation, and spacing of the slots, a variety of radiation patterns can be obtained. A summary of the possibilities, together with sketches of some slot configurations, appear on pages 16-33 and 16-34 of Zucker.¹³ This antenna was proposed for application to millimeter waves, but its concept was not reintroduced until interest in millimeter waves was revived 15 years or so later.

The second antenna structure was called the *sandwich-wire antenna*, and its configuration was an outgrowth of stripline. There are two versions. In the first configuration,²⁹ the top and bottom plates and the center strip of stripline are each reduced to wires, and the center wire is then snaked along its length in periodic fashion. The periodicity is selected so that the $n = -1$ space harmonic can radiate. A second configuration³⁰ looks more like a suspended microstrip line that is cavity-backed, with a strip mounted on a cavity-backed thin dielectric layer, to support the strip, and with the strip undulating sinusoidally back and forth along the dielectric layer. Again, the $n = -1$ space harmonic radiates, and measurements were made to determine the performance properties. Diagrams of the structures and curves for some measurements may be found on pages 16-36 and 16-38 of Zucker.¹³ A limitation on the usefulness of this antenna approach is that dimensional changes that affect β affect α as well. For example, a good approximation for the relative phase velocity is obtained by assuming that the wave velocity along the undulating strip is that of light. Thus if the amplitude of the undulation is increased, the value of β will be increased. However, the value of α is changed most easily by varying that same amplitude.

Periodic Dielectric Waveguides

Periodic dielectric waveguides are uniform dielectric waveguides with a periodic surface perturbation. Several types of uniform dielectric waveguides are shown in cross section in Figure 11-10a through e. Rectangular shapes are preferred for antennas of this class. The type in Figure 11-10a is a simple rectangular rod of rectangular shape; the type in Figure 11-10b is a rectangular form of dielectric image guide; and the type in Figure 11-10c, the insular guide, has an extra dielectric layer on the ground plane so as to reduce the ground-plane losses. The types in Figure 11-10d and e, the trapped image guide³¹ and the inset guide,³² respectively, lend themselves to a flush-mounted arrangement and reduce radiation losses from bends. The two most common dielectric waveguides are the types in Figure 11-10a and b.

The most common periodic modulation methods are a grating of grooves, a grating of metal strips, and, to a lesser extent, a series of metal disks. These perturbations are ordinarily placed on the top surface (the wide dimension) of these guides, but they also may be placed on the sides,

FIGURE 11-10 Cross sections of several types of uniform dielectric waveguides: (a) rectangular rod of rectangular shape; (b) rectangular form of dielectric image guide; (c) the insular guide, with an extra dielectric layer of lower ϵ_r on the ground plane; (d) trapped image guide; (e) inset guide

FIGURE 11-11 Dielectric image guide with (a) a grating of grooves and (b) a grating of metal strips

when accessible. Dielectric image-guide antennas with a grating of grooves and with a grating of metal strips appear in Figure 11-11a and b, respectively. These gratings are shown as uniform; in practice, the gratings would be tapered so that the groove depths and the metal strip widths would be very small at the beginning and the end in each case.

The antennas in Figure 11-11a and b were first proposed around 1960, but systematic investigations of their behavior, both experimental and theoretical, were not carried out until the late 1970s. Most of the early studies were conducted by the army at Ft. Monmouth, on grooved antennas^{33–35} and on antennas with metal strips.^{36–38} Experimental studies on the metal-strip antennas were also performed at the University of Illinois^{39–41} during this period on dielectric image guide, and by Itoh and Adelseck⁴² on trapped image guide. One important conclusion from the Ft. Monmouth studies was that in practice there is an upper limit to the value of leakage constant obtainable with grooved gratings; antennas employing grooved gratings were therefore limited to narrow radiated beams. It was found that the metal-strip gratings were more versatile, permitting both wide and narrow beams.

Studies also were concerned with how these antennas could be fed without causing spurious radiation at the feed.^{40,43} Solbach⁴³ utilizes slots cut into the ground plane under the dielectric rectangular rod to effect a smooth transfer of power from the feedline.

The radiation pattern in the cross-plane depends on the width of the dielectric structure. The waveguide is excited in its dominant mode, and its width is usually chosen to be comparatively small so as to avoid excitation of higher-order modes. Alternatively, if you wish to narrow the beam in the cross-plane, the dielectric width may be made large, but then single-mode excitation must be ensured by an appropriate feed arrangement. Another technique⁴¹ is shown in Figure 11-12. The grating structure is embedded in a rectangular metal trough, which is then attached to a flared-horn configuration; design details are included in Trinh et al.⁴¹

Design Theory for Wide Periodic Dielectric Antennas

Starting in the late 1970s accurate theoretical analyses became available that permit the systematic design of this class of leaky-wave antennas. For antennas employing a *grating of grooves*, thorough and detailed studies were performed by Schwering and Peng,^{7,33,34} based in part on earlier analytical work by Peng and Tamir.^{44,45} The two best sources for systematic design information are Schwering and Peng⁷ and Schwering and Oliner.⁴⁶ Corresponding, but less thorough,

FIGURE 11-12 The use of a flared horn in conjunction with the structure in Figure 11-11b to narrow the beamwidth in the cross-plane (after Trinh et al.⁴¹ © IEEE 1981)

design information on *metal-strip-grating antennas* comes mostly from work by Guglielmi and Oliner,⁴⁷ based on earlier analyses by them⁴⁸⁻⁵⁰ of scattering by metal strip gratings on a dielectric substrate. Another accurate method of analysis for these antennas was presented by Encinar.⁵¹ Many of the general conclusions appropriate to grooved antennas, however, apply as well to those with metal-strip gratings. The detailed expressions for β/k_0 and α/k_0 are different, of course.

The theoretical design information referred to earlier is applicable directly to dielectric image guides, i.e., structures for which a ground plane is present under the rectangular dielectric layer. The procedure is readily extendable to structures without a ground plane, however, by some suitable, basically straightforward modifications. The numerical values presented in Schwering and Peng⁷ and Schwering and Oliner⁴⁶ assume that the dielectric material has an $\epsilon_r = 12$, corresponding to Si or GaAs, so that the antenna performance can be controlled, if desired, by semiconductor devices.

For the antenna employing a *grating of grooves*, the groove depth must be chosen to lie within a certain range if we wish to optimize the leakage constant α . The reason for this can be understood physically in a simple way. Consider the structure shown in the inset in Figure 11-13, where the height of the uniform dielectric region is h and the groove depth is t . Suppose that we maintain the sum of $h + t$ constant and we increase the groove depth t . Although the total antenna height is fixed, the effective dielectric constant ϵ_{eff} of the structure is decreased as t is increased, because the groove region is

FIGURE 11-13 Calculations for the normalized leakage constant and the radiation angle as a function of groove depth for the dielectric image guide with a grating of grooves shown in Figure 11-11a (after Schwering and Peng⁷ © IEEE 1983)

now partly air-filled. The value of ϵ_{eff} , combined with the height $h + t$, may be viewed as an “effective height” and is an important design parameter. When the effective height is small, most of the guided energy travels in the air region above the antenna, and the grooves would cause little radiation. When the effective height is large, on the other hand, the energy is confined primarily to the interior of the antenna, and again the grooves will have little effect. An intermediate effective height thus exists for which the energy density in the grooved region reaches a peak value. We would therefore expect that α could be maximized by an optimal combination of groove depth and effective height. The curve of $\alpha\lambda_0$ versus t/λ shown in Figure 11-13 illustrates precisely such behavior for the structure treated there. Similar qualitative reasoning applies to other periodically modulated open dielectric structures.

Design Theory for Narrow Periodic Dielectric Antennas

The theoretical results referred to in the above subsection make the assumption that the dielectric structures have infinite width w . It has been found, however, that they apply quite accurately to “wide” structures, for which $w > \lambda_0 / \sqrt{\epsilon_{\text{eff}} - 1}$. If $\epsilon_{\text{eff}} = 2$, for example, these results are applicable to antennas for which $w > \lambda_0$. For $\epsilon_{\text{eff}} = 6$, on the other hand, w need satisfy only $w > 0.45\lambda_0$. Thus the theory for “infinite” width can actually be applied with good accuracy to structures that are fairly narrow. When the antennas are narrower than the criterion just mentioned will allow, a correction scheme is available that yields accurate results for them as well.

For antennas of narrow width ($w < \lambda_0 / \sqrt{\epsilon_{\text{eff}} - 1}$), the value of β can be derived in a simple way with good accuracy by using the EDC (equivalent dielectric constant) procedure, but α can no longer be approximated by that of an infinitely wide antenna with the same dielectric constant as the finite antenna. As w decreases, the phase velocity of the leaky mode increases, so that an increasing portion of the guided energy now travels in the air regions on both sides in the neighborhood of the perturbing mechanism, whether grooves or metal strips. As a result, the leakage constant α of the narrower antenna becomes smaller.

A simple procedure has been developed⁵² that employs the EDC method to replace the antenna of finite width by an equivalent antenna of infinite width, but with a lower effective dielectric constant. As a result, a lower value of α is obtained. This procedure has produced numerical values for α and β that have agreed very well with measured results for a quite narrow antenna, with $\epsilon_r = 16$ and $w = 1.3$ mm, in the frequency range from 30 to 36 GHz.⁵² Some details regarding this procedure may also be found in Schwering and Oliner,⁴⁶ pages 17-64 to 17-68.

Periodic Leaky-Wave Antennas Based on Microstrip Line

A wide variety of possible traveling-wave periodic array antennas can be achieved by employing microstrip line. As examples, we can employ a series of resonant patch antennas connected by the microstrip line, as seen in Figure 11-14a, or a series of array elements coupled by proximity to the

FIGURE 11-14 Top views of traveling-wave periodic array antennas based on microstrip line: (a) series of resonant patch antennas connected by microstrip line; (b) series of elementary radiators, resonant or not, coupled by proximity to the microstrip line (after James et al⁵³)

microstrip line, as shown in Figure 11-14*b*. Top views of the structures are presented. Another wide class of possibilities is illustrated in Figure 11-15*a* through *c*, and these involve periodic meanderings of the microstrip line strip itself. These last structures are reminiscent of the sandwich-wire antenna^{29,30} described earlier in the subsection “Early Structures.” These and other traveling-wave arrays based on microstrip line are discussed in detail in the two comprehensive books^{53,54} on microstrip antennas by James et al and by James and Hall, respectively. The original references for the antennas in Figure 11-14*a* and *b* are Derneryd⁵⁵ and Cashen et al,⁵⁶ respectively.

No theory is available for most of these antennas. For the few structures, such as the one shown in Figure 11-14*a*, for which some theory is available, the theory is of the type used to describe the behavior of slot arrays. All the thinking, in fact, parallels that employed for slot arrays. For example, the array elements are usually assumed to be individually resonant, although there is no reason why they need to be. The theory then treats each element as loading the line individually, instead of viewing the structure in leaky-wave fashion. (See the discussion in Section 11.1 on the relation between leaky-wave antennas and slot arrays.) Furthermore, in many cases the arrays are designed to be resonant (standing wave rather than traveling wave). The array in Figure 11-14*a* is specified as a resonant one, but an interesting traveling-wave modification has been reported.⁵⁷ This modification contains additional phase shift between successive elements to reduce the frequency change needed to cover a given range of scan angle.

These same structures can be transformed into standard leaky-wave antennas by simply making the individual radiating elements nonresonant (so each loads the line less strongly) and changing the spacing between elements to produce a traveling-wave rather than a standing-wave array. Then the structure would lend itself to a leaky-wave analysis, although such an analysis has not yet appeared.

FIGURE 11-15 Examples of periodic leaky-wave antennas based on microstrip line where the microstrip line itself is meandered periodically: (a) sinusoidal, (b) trapezoidal, and (c) zigzag (after James et al⁵³)

Periodic Arrays of Microstrip Patches or Dielectric Resonators Fed by Open Dielectric Waveguides

Since microstrip line becomes increasingly lossy as the frequency is raised, several investigators have built and measured antennas designed for use at millimeter wavelengths in which the microstrip line is replaced by a dielectric waveguide as the transmission line that feeds the periodic radiating elements. The viewpoint is that the feedline can be considered separately from the radiating elements, so that a less lossy feedline can be employed at the higher frequencies. The resulting antennas are indeed less lossy, but they sometimes become hybrid in character.

An example of such antennas is shown in Figure 11-16. The radiating elements here are microstrip patch resonators, and they are fed by a low-loss open dielectric waveguide in the form of insular guide. The fringing fields of the dielectric guide excite the microwave patches. It is interesting that this mechanism is the same as the one used many years ago²⁸ with dielectric image line, discussed earlier in the subsection “Early Structures.” In addition to low loss, this antenna has the advantage of simplicity. In an experimental design^{58,59} the distance between the metal patches and the dielectric guide is varied along the length to produce a taper to control the sidelobe level, as seen in Figure 11-16*b*. Nevertheless, the design was purely empirical, since no theory was available, and the resulting radiation-pattern performance was only mediocre.

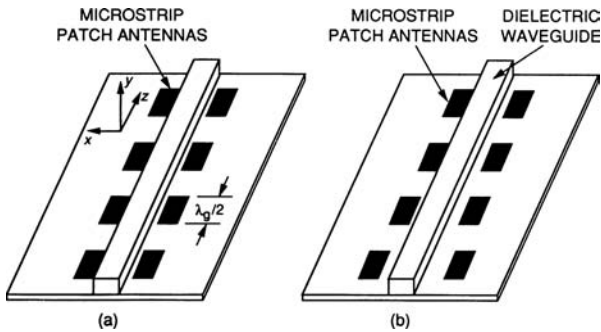

FIGURE 11-16 A hybrid form of periodic leaky-wave antenna in which microstrip patch resonator arrays are fed by a dielectric image guide: (a) basic configuration; (b) configuration including a taper to control the sidelobes (after James and Henderson⁵⁹)

At about the same time, another study⁶⁰ replaced the microstrip patches by dielectric resonators, which may take the form of small rectangular or cylindrical dielectric blocks. The same type of open dielectric waveguide served as the feed transmission line. Again, however, the design was only empirical, and the pattern performance was therefore only marginal.

11.7 SPECIFIC STRUCTURES BASED ON UNIFORM OPEN WAVEGUIDES

As indicated in Section 11.5, almost all the early uniform leaky-wave antennas were based on initially closed waveguides. Those antennas were conceptually simple, and they worked very well. It was only much later, in response to requirements at millimeter wavelengths, that thought was given to leaky-wave antennas based on uniform *open* waveguides. There exists one notable exception, and that case is discussed later in the subsection “Early Structure: Asymmetrical Trough Waveguide Antenna.”

There were two reasons why new types of leaky-wave antennas were sought for the millimeter-wave region. The first relates to the small wavelengths in this region; to minimize fabrication difficulties, the new antennas had to be *simple* in configuration, and *uniform* guiding structures satisfied this condition. The second reason was that the usual waveguides had higher *loss* at these higher frequencies; as a result, the new antennas were generally based on new lower-loss waveguides that had been studied specifically for application to the millimeter-wave region. These waveguides were *open* so that part of the field extended into the air region outside, thereby reducing the energy density and the loss. The principal waveguides in this category were nonradiative dielectric (NRD) guide and groove guide.

Because of the open nature of these waveguides, new mechanisms had to be found to produce the leakage. A physical cut is not meaningful because the structure is already open. Three main mechanisms were employed: (1) introducing asymmetry in the structure so that a radiating component of field is created, (2) foreshortening some dimension in the cross section, and (3) using a higher-order mode that is leaky in itself, rather than the bound dominant mode. The mechanism most commonly employed then and today is asymmetry.

Many geometric arrangements can be devised that satisfy the preceding requirements and make use of one of the leakage mechanisms listed, but we must remember that the resulting structures also must be analyzable so that the antennas can be designed systematically

and not simply on an empirical basis, as is true for some of the more novel periodic open leaky-wave antennas discussed in the preceding section. All the uniform open antennas described in this section have been analyzed accurately, and theoretical expressions for their design are available in the literature. Most of the antennas discussed here are due to Oliner, as part of a systematic cooperative investigation with principal colleagues Lampariello of Italy and Shigesawa of Japan. Summaries of their contributions appear in two books^{46,61} and in a review article⁶²; details are contained in individual papers referenced later and in a comprehensive two-volume report.⁶³

Early Structure: Asymmetrical Trough Waveguide Antenna

The first open waveguide that was made leaky by introducing asymmetry in the cross section was the trough waveguide. The antenna structure, shown in Figure 11-17 in full view and in cross section, was invented and measured by Rotman⁶⁴ and analyzed by Oliner⁶⁵ about 40 years ago. It was a practical antenna, widely used, and is still useful today. It appears to be the only early example of the class of uniform leaky-wave antennas based on open waveguides.

The trough waveguide itself, when operated as a nonradiating transmission structure, is symmetrical about the center fin and is derived from symmetrical strip transmission line by placing a short-circuiting plate at its midplane. The dominant mode in the trough waveguide is therefore identical with the first higher-order mode in stripline. Trough waveguide

FIGURE 11-17 The uniformly asymmetrical trough waveguide antenna: (a) full view and (b) cross section for zero-thickness center fin showing the electric field orientations (after Rotman and Oliner⁶⁵ © IRE (now IEEE) 1959)

therefore combines the mechanical simplicity of a stripline with the frequency characteristics of a waveguide, and its bandwidth for single-mode propagation is greater than that for rectangular waveguide by about 50 percent. It also can be coupled smoothly to a coaxial line, a feature that makes it convenient for use at lower frequencies.

Despite the fact that trough waveguide is open on one side, it is nonradiating when the structure is symmetrical. The introduction of asymmetry, however, will produce radiation in a leaky-wave fashion. In fact, one virtue of this type of leaky-wave antenna is the simple means by which radiation can be controlled. The asymmetry can be varied, for example, by placing a metal insert in one of the halves of the line, as shown in Figure 11-17, and adjusting its thickness d .

A theoretical analysis⁶⁵ employing transverse resonance together with a perturbation treatment yields the following simple expressions for the leaky-wave propagation characteristics:

$$\frac{\lambda}{\lambda_g} = \frac{\lambda}{\lambda_{g0}} - \frac{\lambda}{2\pi} \frac{\lambda_{g0}}{\lambda_{c0}} \text{Re}(\Delta\kappa) \quad (11-31)$$

and

$$\alpha = \frac{\lambda_{g0}}{\lambda_{c0}} \text{Im}(\Delta\kappa) \quad (11-32)$$

where

$$\text{Re}(\Delta\kappa) = \frac{\pi d}{4L_1L_2} \left(1 - \frac{d}{L_1 + L_2} \right) \quad (11-33)$$

and

$$\text{Im}(\Delta\kappa) = \frac{(\pi d)^2}{8L_1L_2(L_1 + L_2)} \quad (11-34)$$

with

$$L_1 = s_1 + \frac{2b}{\pi} \ln 2 \quad (11-35)$$

and

$$L_2 = s_2 + \frac{2b}{\pi} \ln 2$$

The structural dimensions s_1 , s_2 , d , and b are indicated in Figure 11-17; λ_{c0} and λ_{g0} are the cutoff wavelength and guide wavelength respectively of the symmetrical and therefore nonradiating trough waveguide.

These expressions have been found to give rather good agreement with measured values,⁶⁵ especially for narrow radiated beams. For wider beams it is better to use the transverse resonance expression itself (without the perturbation simplifications), which is also given and derived in Rotman and Oliner.⁶⁵ Numerical data for various parameter combinations, and corrections to be made for center fins of appreciable thickness, are also found in this reference.

Foreshortened-Top NRD Guide Antenna

Nonradiative dielectric (NRD) guide is a low-loss open waveguide for millimeter waves that was first proposed and described in 1981.⁶⁶ It is a modification of H guide where the

FIGURE 11-18 The nonradiative dielectric (NRD) guide, on the left, and the foreshortened-top leaky-wave antenna based on it, on the right (after Sanchez and Oliner⁶⁷ © IEEE 1987)

spacing between the metal plates is less than $\lambda_0/2$ so that all junctions and discontinuities that maintain symmetry become purely reactive instead of possessing radiative content. The waveguide structure is shown on the left-hand side of Figure 11-18. The dielectric material in the center portion confines the main part of the field, and the field decays exponentially in the vertical direction in the air region away from the dielectric-air interfaces. Two new leaky-wave antennas are based on this waveguide: the foreshortened-top NRD guide antenna and the asymmetrical NRD guide antenna. The former antenna is discussed now, and the latter one is treated in the next subsection.

When the vertical metal plates in the NRD guide are sufficiently long, as shown on the left-hand side of Figure 11-18, the dominant mode field is effectively completely bound, since the field has decayed to negligible values as it reaches the upper and lower open ends. If the upper portion of the plates is foreshortened, as seen on the right-hand side of Figure 11-18, the field is still finite at the upper open end (but negligible at the lower open end). A traveling-wave field of finite amplitude then exists along the length of the upper open end, and, if the dominant NRD guide mode is fast (it can be fast or slow depending on the frequency), power will be radiated away at an angle from this open end.

An accurate theory was developed by Sanchez and Oliner,⁶⁷ in which an accurate transverse equivalent network was developed for the cross section of the antenna, and the dispersion relation for the values of α and β was obtained from the resonance of this network. All the elements of this dispersion relation are in closed form, thus permitting easy calculation. The leakage constant α is determined simply by the amount of foreshortening, measured by d , and β is essentially unaffected by changes in d unless d becomes very small. Thus α and β can be adjusted independently, to a great extent, which is very desirable because the procedure for sidelobe control is then simplified.

Careful measurements were taken by Yoneyama⁶⁸ at 50 GHz and by Han et al⁶⁹ in the vicinity of 10 GHz on a scaled structure. Excellent agreement between measurement and theory was found over the range of parameter values examined, and results for one case are given on Figure 11-19. You also can see that α can be varied over an extremely wide range, permitting narrow beams or wide beams, simply by altering the value of d .

The amplitude distribution in the radiating aperture can be controlled by varying the distance d as a function of the longitudinal coordinate z . This may be accomplished either by appropriately shaping the upper edge of the metal plates or by slightly curving the dielectric strip so that its distance from the edge of the plates varies in a prescribed fashion with z ; the edge in this case would be straight. The latter procedure leads to a very simple and easy-to-build antenna configuration, which is indicated in Figure 11-20. Furthermore, the antenna is directly compatible with transmit and receive circuits designed in NRD guide technology. The antenna radiates with vertical polarization in the principal plane.

FIGURE 11-19 Comparison between measurement and theory for the leakage constant as a function of the length d of the foreshortened top for the NRD guide leaky-wave antenna shown in Figure 11-18 (after Han et al⁶⁹ © IEEE 1987)

FIGURE 11-20 Side view of the foreshortened-top NRD guide leaky-wave antenna, showing how the value of α can be tapered very easily to reduce the sidelobes (after Sanchez and Oliner⁶⁷ © IEEE 1987)

Asymmetrical NRD Guide Antenna

The leakage mechanism for this NRD guide antenna is different from that for the antenna described just above, since this one is based on asymmetry, as shown in Figure 11-21. The structure shown on the left-hand side of Figure 11-18 is first bisected horizontally to provide radiation from one end only. Since the electric field is purely vertical in this midplane, the field structure is not altered by the bisection. An air gap is then introduced into the dielectric region, as shown, to produce asymmetry. As a result, a small amount of net horizontal electric field is created, which produces a mode in the parallel-plate air region akin to a TEM mode. This mode then propagates at an angle between the parallel plates until it reaches the open end and leaks away. It is necessary to maintain the parallel plates in the air region sufficiently

long that the vertical electric field component of the original mode has decayed to negligible values at the open end. Then the TEM-like mode, with its horizontal electric field, is the only field left, and the field polarization is then essentially *pure*. (The discontinuity at the open end does not introduce any cross-polarized field components.)

The asymmetry mechanism applied to the NRD guide in this way furnishes another leaky-wave antenna of simple configuration, but now with pure horizontal polarization. The air gap does not have to be large to produce a significant leakage rate. The geometry can thus be controlled easily to achieve a large range of values for α and, therefore, a large range of desired beamwidths. Furthermore, the air gap affects β only slightly, so that β and α can be controlled relatively independently. Of course, the guide must be operated in the fast-wave range to produce radiation.

The theory^{70,71} for this structure employs mode matching at the air-dielectric interfaces, and numerical results were obtained as a function of the geometric parameters. A detailed presentation of the theory and various numerical results appear in Chapter III of a comprehensive report.⁶³ No measurements have been taken to verify the theory.

There are many ways in which asymmetry can be introduced; this one was chosen for inclusion here because theoretical results are available for it. Measurements are available for a structure in which the asymmetry was produced by sloping the upper dielectric-air interface rather than introducing an air gap. Those measurements⁷² shown that radiation indeed occurs and that good patterns result, but parameter optimization has not yet been accomplished and no theory is available.

FIGURE 11-21 The asymmetrical NRD guide leaky-wave antenna produced by creating an asymmetrical air gap of thickness t and bisecting the NRD guide horizontally. The modifications introduced in the electric fields are also shown (after Oliner,⁶³ with Xu).

Stub-Loaded Rectangular Waveguide Antenna

The leaky-wave antenna whose cross section is shown in Figure 11-22 was derived from earlier work on groove guide, and its early name was the *offset-groove-guide antenna*.

FIGURE 11-22 Cross section of the stub-loaded rectangular waveguide antenna, which has a remarkable set of important virtues. This antenna was earlier called the offset-groove-guide antenna (after Oliner,⁶³ with Lampariello and Shigesawa).

Under that name several presentations were made,⁷³⁻⁷⁵ and a full description was given in Chapters VII and VIII of Oliner.⁶³ Numerical results were derived for several different cross-sectional ratios, and some of the best performance was found for an aspect ratio corresponding to that for rectangular waveguide. The structure is also easy to feed from rectangular waveguide. For these reasons, the name was changed to the *stub-loaded rectangular waveguide antenna*, and three comprehensive companion papers⁷⁶⁻⁷⁸ were written with the new name.

Groove guide is a low-loss open waveguide for millimeter waves somewhat similar to the H guide or NRD guide; the dielectric central region of NRD guide is replaced by an air region of greater width. The fields are again strongest in the central region, and they decay exponentially vertically in the regions of narrower width above and below. Groove guide was popular some years ago, but it lost its glamour when it was realized that its higher-order modes would radiate, so that discontinuities in the guide would have some resistive content. This feature limited the range of applications for which groove guide was suitable, but it did not influence its application to leaky-wave antennas.

This antenna has a remarkable set of unusual virtues. One of the virtues is its versatility, which may be understood from the following considerations. When the stub is centered, the structure becomes nonradiating; alternatively, it may be viewed then as a slotted section cut in rectangular waveguide. For small off-center positions of the stub, the leakage rate will be small, yielding radiated beams of narrow width. When the offset is increased, α will increase, and the beamwidth will increase. We therefore have a relatively simple leaky-wave antenna, easily fed from a rectangular waveguide, that permits great versatility with respect to beamwidth by simply adjusting the location of the stub guide.

Even more important, it is found that the value of β changes very little as the stub is moved, while α varies over a very large range. This feature, namely, that β remains almost constant while α varies, makes it easy to taper the antenna aperture to control sidelobes. Thus it should be easy with this antenna to design beams with low sidelobe levels.

An additional advantage follows from the fact that the antenna is filled with only one medium, namely, air. As was shown in Section 11.2, the beamwidth then remains constant when the beam is scanned in elevation as you change the frequency.

The antenna was analyzed using a transverse equivalent network based on a new E -plane T -junction network.⁷⁹ This T -junction network is notable in that the expressions for the network elements are all in simple closed form and yet are very accurate. The resulting transverse equivalent network for the antenna is seen in Figure 11-23. Since the network elements are in closed form, the resonance relation for the complex propagation wave number is also in closed form, making calculations quick and easy.

FIGURE 11-23 The transverse equivalent network for the antenna structure in Figure 11-22. Closed-form expressions for the network elements are given in the text.

The expressions for the elements of the network in Figure 11-23 may be written as

$$\frac{B_a}{Y_0} = -\frac{\pi}{16} \frac{a'}{b} \frac{k_x a'}{2} J_0^2\left(\frac{k_x a'}{2}\right) \quad (11-36)$$

where J_0 is the Bessel function of zero order,

$$\frac{B_L}{Y_0} + \frac{1}{2} \frac{B_a}{Y_0} = \frac{1}{n_c^2} \left(\frac{k_x b}{\pi}\right) \left[\ln\left(1.43 \frac{b}{a'}\right) + \frac{1}{2} \left(\frac{k_x b}{\pi}\right)^2 \right] \quad (11-37)$$

$$n_c = \frac{\sin(k_x a' / 2)}{k_x a' / 2} \quad (11-38)$$

$$n_{cs}^2 = n_c^2 (a' / b) \quad (11-39)$$

$$\begin{aligned} \frac{B_L}{Y_0} = & \frac{1}{n_c^2} \left(\frac{k_x b}{\pi}\right) \left[\ln\left(1.43 \frac{b}{a'}\right) + \frac{1}{2} \left(\frac{k_x b}{\pi}\right)^2 \right] \\ & + \frac{\pi}{32} \frac{a'}{b} \left(\frac{k_x a'}{2}\right) J_0^2\left(\frac{k_x a'}{2}\right) \end{aligned} \quad (11-40)$$

so that the dispersion relation for the transverse wave number k_x becomes

$$\frac{1}{n_{cs}^2} + j \frac{B_L}{Y_0} + j \frac{\left[\frac{B_a}{Y_0} - \cot k_x \left(\frac{a'}{2} + d\right) \right] \left[\frac{B_a}{Y_0} - \cot k_x \left(\frac{a'}{2} + d'\right) \right]}{2 \frac{B_a}{Y_0} - \left[\cot k_x \left(\frac{a'}{2} + d\right) + \cot k_x \left(\frac{a'}{2} + d'\right) \right]} = 0 \quad (11-41)$$

where the wave number k_x is related to k_z , the result that we seek, by

$$k_z = \beta - j\alpha = \sqrt{k_0^2 - k_x^2} \quad (11-42)$$

These expressions, and the transverse equivalent network in Figure 11-23, assume that the stub guide is infinite in length. In practice, of course, the stub length is finite, and it should only be long enough that the vertical electric field (represented in the stub guide by the below-cutoff TM_1 mode, viewed vertically) can decay to negligible values, permitting essentially pure horizontally polarized radiation. Usually, the stub length need only be about a half wavelength or less if the stub is narrow. The finite stub length can be readily taken into account, and a detailed treatment of its effects is reported in Oliner,⁶³ but it produces only a small change in the numerical values obtained from the procedure given earlier.

FIGURE 11-24 Comparison of numerical results for the stub-loaded rectangular waveguide antenna, obtained via two completely different theoretical methods. Additionally, we see that by varying the offset d , we can change α over a wide range of values while affecting β very little. Such independence makes it easy to taper the aperture distribution in order to control the sidelobes. $f = 28$ GHz, $a = 1.0$ cm, $a' = 0.7$ cm, $b = 0.3$ cm (after Oliner,⁶² with Shigesawa).

As an independent check on the accuracy of these expressions, the values of α and β were calculated using an entirely different theoretical approach, that of mode matching. As shown in Figure 11-24, where the dashed lines represent values obtained using the network and the solid lines represent those derived via the mode-matching procedure, the agreement is seen to be very good. We also can see from this figure that, as the stub is shifted laterally, β remains almost constant as α varies monotonically from zero to large values.

Measurements were also taken of the values of α and β and of the radiation patterns over the frequency range from 40 to 60 GHz.⁷⁸ A photograph of the cross section of the structure appears in Figure 11-25. The Japanese 500-yen coin (26.5 mm in diameter) is seen to dwarf the antenna cross section. The comparisons between the theoretical and measured values for both α and β are found to be very good.

The stub-loaded rectangular guide leaky-wave line source antenna is thus an attractive structure for millimeter wavelengths, since it is simple in configuration, easily fed, versatile in beamwidth, suitable for low-sidelobe-level designs, and capable of furnishing essentially pure horizontally polarized radiation. In addition, a simple and accurate theory is available for it that has been verified by an alternative, totally different computational approach, as well as by measurements.

FIGURE 11-25 Photograph of the cross section of a stub-loaded rectangular waveguide antenna that was measured at millimeter wavelengths. A 500-yen Japanese coin (26.5 mm in diameter) is shown for size comparison (after Oliner,⁶³ with Shigesawa).

Printed-Circuit Version of Stub-Loaded Rectangular Waveguide Antenna

If the versatile leaky-wave antenna just described could be made in printed-circuit form, the fabrication process could make use of photolithography, and the taper design for sidelobe control could be handled automatically in the fabrication. That is, the location and width of the stub, and their variations along the antenna length in conformity with the sidelobe design requirements, could all be accomplished at the same time by either depositing the metal or etching some away to produce the gap. With this goal in mind, a printed-circuit version of the structure in Figure 11-22 took the shape shown in Figure 11-26.

The principal change is that the rectangular guide portion is now dielectric-filled so that the metal widths d' and d and the gap a' can be fabricated photolithographically. Also, the vertical baffle portions are now moved to the sides of the guide, as extensions of the guide side walls.

The basic physics of the leakage is the same as that for the antenna in Figure 11-22. The rectangular guide, now dielectric-filled, is fed from one end with the electric field vertical inside the guide. This vertical E field excites the asymmetrically located longitudinal slot such that the resultant field in the slot has both vertical and horizontal components. These field components in turn excite the TM_1 mode (viewed vertically) and the TEM mode (at an angle) respectively, in the parallel-plate air-filled stub region. The separation a between the stub walls is less than a half wavelength, so that the TM_1 mode is below cutoff; the TEM mode, being above cutoff, propagates at an angle to the upper end and radiates. The stub dimension c must then be sufficiently long that the field of the TM_1 mode can

FIGURE 11-26 Printed-circuit version of the stub-loaded rectangular waveguide antenna shown in Figure 11-22. This version has the advantage that the tapering to control sidelobes can be effected photolithographically all at one time (after Oliner,⁶³ with Lampariello and Frezza).

FIGURE 11-27 Variations of the beam angle θ_m and the beamwidth $\Delta\theta$ as a function of the relative slit width for the printed-circuit structure in Figure 11-26. It is seen that as a'/a varies from about 0.4 to about 0.8, the beamwidth changes over a wide range while the beam angle remains almost constant, showing that a' is a good parameter to vary to reduce the sidelobes. $f = 50$ GHz, $\epsilon_r = 2.56$, $a = 2.25$ mm, $b = 1.59$ mm, $d = 0.20$ mm (after Oliner,⁶³ with Lampariello).

decay to negligible values. As a result, the radiated power is polarized horizontally, with negligible cross-polarization. It would be nice to eliminate the vertical stub walls, but they are necessary for eliminating the vertical electric field component.

The transverse equivalent network for this new antenna structure is slightly more complicated than the one in Figure 11-23, and the expressions for the network elements must be modified appropriately to take the dielectric medium into account. The detailed derivation of the modified network and the expressions for the network parameters appears in Chapter X of Oliner.⁶³

Again, α can be varied by changing the slot location d . However, it was found that a' is also a good parameter to change for this purpose. The variations in beam-elevation angle θ_m and beamwidth $\Delta\theta$ with relative slot width a'/a are presented in Figure 11-27. You can see that as a'/a varies from about 0.4 to about 0.8, the beamwidth changes from about 4° to nearly zero but that the beam location moves hardly at all over that range. The slot width a' therefore represents a good parameter to vary to control the sidelobes.

This antenna structure has not yet been examined experimentally, but it appears to be a very promising one.

An interesting variation of the structures shown in Figures 11-22 and 11-26 has been developed and analyzed.⁸⁰ It is based on a ridge waveguide rather than a rectangular waveguide, and the structures can be either air-filled or dielectric-filled. In the structures based on rectangular waveguide, the asymmetry was achieved by placing the stub guide, or locating the longitudinal slot (or slit), off-center on the top surface. Here the top surface is symmetrical, and the asymmetry is created by having unequal stub heights on each side under the main guide portion.

By a clever arrangement of the geometry, the coauthors, Frezza, Guglielmi, and Lampariello,⁸⁰ were able to vary the values of α and β essentially independently by adjusting combinations of the vertical stubs. Let us define two geometric parameters: (1) the relative average arm length b_m/a , where $b_m = (b_l + b_r)/2$, and b_l and b_r are the left and right stub arm lengths; (2) the relative unbalance $\Delta b/b_m$, where $\Delta b = (b_l - b_r)/2$. It then turns out that by changing b_m/a , you can adjust the value of β/k_0 without altering α/k_0 much and that by changing $\Delta b/b_m$, you can vary α/k_0 over a large range without affecting β/k_0 much. In this way, by changing only the stub lengths, you can exercise essentially independent control over β and α . The taper design for controlling the sidelobe level would therefore involve only the relative unbalance, $\Delta b/b_m$.

The air-filled ridge waveguide structure may therefore have a constructional advantage regarding sidelobe control over the simpler structure shown in Figure 11-22. However, the dielectric-filled ridge waveguide antenna lacks the important advantage offered by the printed-circuit version in Figure 11-26, for which you can make a mask that permits the whole upper surface, including the taper for sidelobe control, to be realized photolithographically.

11.8 ARRAYS THAT SCAN IN TWO DIMENSIONS

All the leaky-wave antennas discussed so far in this chapter are line-source antennas that produce conical beams. They can scan in elevation (or azimuth if they are rotated, of course) as the frequency is varied, with their beamwidths narrow in elevation but wide in the cross-plane. General comments along these lines were made earlier, and it was pointed out that the beamwidth in the cross-plane could be narrowed by using a horn (see Figure 11-12) or by arranging a parallel set of these line sources in an array. Such arrays, however, do not scan in the cross-plane.

This section describes some of the most recent developments involving leaky-wave antennas, where an array of leaky-wave line sources is so arranged that it can scan in both elevation and azimuth. Such an array is really a linear phased array of leaky-wave

line-source antennas, where scanning in elevation is obtained in the usual leaky-wave fashion by varying the frequency, and scanning in the cross-plane (or azimuth) is achieved by varying the phase difference between the successive parallel leaky-wave line sources. The approach itself is not new, but the specific structures are. As will be seen, these arrays have some unusual virtues: essentially no cross polarization, no grating lobes, no blind spots within the scan volume, and simplicity of structure. In addition, they should cost less than phased arrays because phase shifters are needed in only one dimension. These different array structures will be discussed, but first we present the principle of operation (the basic architecture for such arrays) and some comments about the analytical approach, which takes into account all mutual coupling effects.

Principle of Operation

This class of scanning arrays achieves scanning in two dimensions by creating a one-dimensional phased array of leaky-wave line-source antennas. The individual line sources are fed from one end and are scanned in elevation by varying the frequency (or by electronic means if and when available). Scanning in the cross-plane, and therefore in azimuth, is produced by phase shifters arranged in the feed structure of the one-dimensional array of line sources. This frequency-phase scan architecture is illustrated schematically in Figure 11-28.

The radiation will therefore occur in pencil-beam form and will scan in both elevation and azimuth in a conical-scan manner. The spacing between the line sources is chosen such that no grating lobes occur, and accurate analyses show that no blind spots appear anywhere. The leaky-wave line-source antennas employed in the three examples of arrays described here are ones we have already discussed earlier or are modifications of them. The advantage of negligible cross polarization at all angles follows from the fact that the individual line-source antennas possess that feature and that the array arrangement does not introduce any cross-polarized components.

In principle, a large variety of different leaky-wave line sources can be used in this array architecture. In fact, however, you must be very selective here, because the line sources must be integrated into the overall geometry if the resulting antenna is to remain simple in configuration. The list is further limited to those structures amenable to analysis because the design requires a theoretical basis. If the radiating portion of a suitable structure in the class can be fabricated by photolithographic means, using a mask, the costs can also be kept down, and the method is amenable to mass-production techniques. Two of the three arrays to be described fall into this category.

FIGURE 11-28 Schematic of the recent approach to simpler 2D scanning, involving a linear phased array of leaky-wave line sources, with frequency scanning in elevation and phase scanning in azimuth (after Oliner,⁶² with Peng).

Analytical Approach

The arrays to be described have been analyzed accurately by a *unit-cell approach* that takes into account all mutual coupling effects. Each unit cell incorporates an individual line-source antenna, but in the presence of all the others. These individual line-source antennas were analyzed using a transverse equivalent network in which the radiating open end was representative of the environment of the *single* lone line source. In the *array* of such line sources, the radiating environment is, of course, quite different, and it will change as the array is scanned in azimuth.

The treatment of the periodic external environment by a unit-cell approach automatically accounts for all mutual coupling effects and provides information on all the effects of scan. The radiating termination on the unit cell modifies the transverse equivalent network, and the resonances of this transverse network yield the properties of the leaky wave guided along the line sources. A key new feature of the array analysis is therefore the determination of the *active admittance* of the unit cell in the 2D environment as a function of scan angle. This active admittance is the input admittance to the external radiating region, and it is appended to the remainder of the transverse equivalent network, the latter being different for each of the arrays to be discussed.

Array of Asymmetrical NRD Guide Line Sources

A cross-sectional view of the linear phased array of asymmetrical NRD guide leaky-wave line sources appears in Figure 11-29. By comparison with the individual line-source antenna in Figure 11-21, it is clear that the array consists of a number of these line sources placed directly next to each other. The line sources provide the elevation pattern, modified by their presence in the array, and the geometry in the plane shown specifies the cross-plane behavior, with the angle of scan determined by the phase shift imposed between successive line sources.

The unit cell for this array is shown in Figure 11-30, where the phase-shift-wall properties depend on the scan angle in the cross-plane. Thus the discontinuity at the end of the stub of length c , and therefore the values of β and α , depend on that scan angle. The analysis proceeds, therefore, by knowing the imposed phase shift between line sources, and, from it and the unit-cell network, by finding β and α in the axial direction. Everything else follows directly from this information.

If the values of β and α did not change with phase shift, the scan would be exactly conical. However, it is found that these values change only a little, so that the deviation from conical scan is small.

We next consider whether blind spots are present. *Blind spots* refer to angles at which the array cannot radiate or receive any power; if a blind spot occurred at some angle, therefore,

FIGURE 11-29 Cross section of linear phased array of asymmetrical NRD guide leaky-wave line sources. The individual line source appears in Figure 11-30 (after Oliner,⁶³ with Xu).

the value of α would rapidly go to zero at that angle of scan. To check for blind spots, we would then look for any sharp dips in the curves of α/k_0 as a function of scan angle. No such dips were ever found. Typical data of this type exhibit fairly flat behavior for α/k_0 until the curves drop quickly to zero as they reach the end of the conical scan range, where the beam hits the ground.

The theoretical analysis and many numerical results appear in Chapter IV of Oliner,⁶³ and a presentation was made.⁸¹

Array of Printed-Circuit Uniform Line Sources

If the leaky-wave line sources in the array were in printed-circuit form, the fabrication process could make use of photolithography, and the taper design for sidelobe control could be handled automatically in the fabrication. The array structure shown in Figure 11-31 fits into this category. It may be seen that the line-source elements in this array are exactly the printed-circuit version of the stub-loaded rectangular waveguide antenna shown in Figure 11-26. The leakage rate, and therefore the beamwidth, can again be controlled by varying the width or location of the gap within each element. And again, the value of β remains almost constant as the gap width or location is varied, so that a taper design for sidelobe control is easy to implement.

The metal fins that project vertically, which may alternatively be called *baffles* or *stubs*, serve two purposes. The first purpose is to ensure *essentially pure horizontally polarized radiation*, with negligible cross polarization. As explained in the discussion associated with Figure 11-27, the fins form a stub guide that is below cutoff for the vertical electric field, thereby permitting only the horizontal electric field to radiate.

The second purpose of the stubs is to *eliminate blind spots*. With the stubs present, we have never found any, and it is known that arrays of this sort with dielectric layers often exhibit them when there are no stubs. A careful examination shows that the stub length should be roughly a half wavelength, which means that the projection is actually rather small, particularly at millimeter wavelengths.

The transverse equivalent network for the unit cell representing the array in Figure 11-31 is very similar to the one for the isolated line-source antenna and differs from it only in the terminating admittance placed on the end of the stub line. This difference is important,

FIGURE 11-30 Unit cell of the linear array of NRD guide line-source antennas shown in Figure 11-29. The phase-shift walls change with scan angle, and their use leads to an analytical approach that takes all mutual coupling effects into account automatically (after Oliner,⁶³ with Xu).

FIGURE 11-31 Cross section of the linear phased array of printed-circuit *uniform* leaky-wave line sources. The individual line-source antenna appears in Figure 11-26 (after Lampariello and Oliner⁸²).

FIGURE 11-32 Variations of the normalized phase constant and leakage constant with phase shift between adjacent line sources (cross-plane scan) for the array appearing in Figure 11-31, showing conical scan and no blind spots. $f = 50$ GHz, $\epsilon_r = 2.56$, $a = 2.25$ mm, $a' = 1.00$ mm, $b = 1.59$ mm, $c = 6.00$ mm, $d = 0.25$ mm (after Lampariello and Oliner⁸²)

however, in that the terminating admittance is a function of scan angle and takes into account the mutual coupling effects of all the neighbors in the array.

As in the case of the array of asymmetrical NRD guide line sources, the value of β/k_0 changes very little with the phase shift between successive line sources, so that as a result, there is little deviation from conical scan. Also, the curve of α/k_0 as the phase shift is changed does not show any sharp dips but remains fairly flat until it drops as the beam approaches the ground at the end of the scan range. Thus no blind spots have ever been observed. Calculated curves for one set of geometric parameters that demonstrate this behavior are given in Figure 11-32.

A summary of the results obtained for this array appears in Lampariello and Oliner,⁸² further results and the details of the theoretical derivation are contained in Chapter X of Oliner.⁶³

Array of Printed-Circuit Periodic Line Sources

The purpose of employing arrays with *periodically* loaded leaky-wave line sources, instead of *uniform* ones like the two discussed earlier, is to *increase the scan-angle coverage*, as will be explained. An example of such an array is given in Figure 11-33. This array can be fed by using a series of dielectric-filled rectangular guides placed on their sides, so that the periodic elements are excited with a horizontal electric field and the array will radiate with pure horizontal polarization.

The individual leaky-wave line sources in this array may at first look like the periodic metal-strip antenna shown in Figure 11-2 and discussed in Section 11.6, but they are not the same because these are excited by a horizontal electric field, parallel to the strips, whereas the antenna in Figure 11-2 is excited by an electric field that is primarily vertical.

The structure in Figure 11-33 is shown with stub guides, or baffles, present.

FIGURE 11-33 Linear phased array of printed-circuit *periodic* leaky-wave line sources, which is capable of a greater scan range than is possible with the arrays containing uniform line sources (after Oliner,⁶³ with Guglielmi)

For this array, the stubs are not necessary to ensure pure horizontally polarized radiation because no component of vertical field is excited. On the other hand, they also ensure that no blind spots will occur. It is possible that no blind spots will be present when the stubs are removed, but we do not know the answer. Certainly, the structure is simpler and easier to fabricate without the stubs. Either way, the printed-circuit nature of the strips on the dielectric surface permits the detailed metal circuit, including the tapering for sidelobe control, to be deposited photolithographically on the dielectric surface.

As discussed elsewhere in this chapter, leaky-wave antennas with uniform apertures can radiate only into the forward quadrant, and they cannot scan too close to broadside or end fire. In the present periodically loaded array, the dominant mode is chosen to be slow so that it is purely bound; the period is then selected relative to the wavelength so that only the $n = -1$ space harmonic becomes radiating. As a result, the array provides greater scan coverage, since the $n = -1$ beam can scan over the complete backward quadrant and part or all of the forward quadrant, depending on the parameters (except for a narrow angular region around broadside).

In the design of this array, it should be remembered that these small slits radiate very weakly. The discussion with respect to both theory and numerical results in Chapter XI of Oliner⁶³ is restricted to such narrower slits and, therefore, narrower beams. A presentation on this antenna was given.⁸³

The three arrays described earlier are examples of how a linear phased array of leaky-wave line sources can be arranged to provide 2D scanning of a pencil beam over a restricted sector of space. In addition, these three arrays possess certain special virtues. They provide essentially pure horizontally polarized radiation, and they exhibit no blind spots or grating lobes.

11.9 NARROW-BEAM ANTENNAS BASED ON A PARTIALLY REFLECTIVE SURFACE

Overview

This class of leaky-wave antennas is based on planar technology, and it offers a simple way to obtain high directivity with a small source. This category is a relatively new one, and the number of antennas that fit into it has grown slowly over time. These antennas bear some resemblance to the classical Fabry-Perot structure in the optics field, but very few actual antennas have developed from it. In fact, as we shall show, in one important case very similar structures have emerged from very different approaches.

The antenna structures in this section are different from those discussed in the rest of this chapter, but they are also leaky-wave antennas, and their performance obeys the fundamental relations described in the earlier sections of this chapter. These antennas are planar in nature, and most of them consist of a metal ground plane with a dielectric layer on it (which may be air) that is covered with a *partially reflective surface or screen* (PRS) on top of the dielectric layer. The partially reflective (or partially transparent) screen can take various forms, such as a stack of one or more dielectric layers, or a metal screen consisting of a periodic array of slots or patches, or an array of parallel wires. Several examples of such structures are shown in Figure 11-34 (where an electric dipole source is shown). The structure is typically excited by a simple source inside the dielectric layer, which may, for example, be a horizontal electric dipole in the middle of the layer or a magnetic dipole on the ground plane. Such sources may be realized in practice by using printed dipoles inside the layer, microstrip patches on the ground plane, slots in

FIGURE 11-34 Examples of PRS-based leaky-wave antennas: (a) The PRS consists of a stack of dielectric layers. (b) The PRS consists of a periodic array of metal patches. (c) The PRS consists of a periodic array of apertures in a metal plate. (d) The PRS consists of a periodic array of closely spaced wires. In each case a dipole source excitation is shown inside the dielectric layer.

the ground plane, or waveguide-fed apertures in the ground plane. Since the fundamental nature of the beamforming is through leaky-wave radiation, the source merely acts as a launcher for the leaky waves.

For a horizontal dipole source, the radiation produced may be a narrow pencil beam pointing at broadside ($\theta_0 = 0$), or a conical beam pointing at any desired scan angle $\theta_0 > 0$. As discussed later, the thickness of the dielectric layer controls the scan angle. For a conical beam, the pattern is usually fairly omnidirectional (azimuthally independent) for small angles θ_0 , but the E - and H -plane beamwidths typically become more different as the scan angle increases. A vertical dipole source can only produce a conical beam (which is omnidirectional) at a scan angle $\theta_0 > 0$. An illustration of these two types of patterns (broadside and conical) is shown in Figure 11-35.

FIGURE 11-35 An illustration of the beam types that can be realized by using a PRS leaky-wave antenna excited by a horizontal dipole source: (a) a pencil beam at broadside and (b) a conical beam pointing at an angle greater than zero. The dipole source launches a radially propagating cylindrical leaky wave, the phase fronts of which are shown by the dashed lines.

Basic Principles of Operation

One of the main differences between this type of structure and the ones considered previously is that the leaky wave on this structure is a 2D cylindrical wave, which propagates outward radially from the source along the interface.⁸⁴ The leaky wave then furnishes a large aperture that in turn produces the narrow radiation beam. As is true for all leaky-wave antennas, the narrow beam angle and the beamwidth are frequency sensitive. A vertical electric or magnetic dipole source launches only a TM_z or TE_z leaky wave respectively, which has no ϕ variation. This results in an omnidirectional conical beam.⁸⁴ A horizontal electric or magnetic dipole source launches a pair of leaky waves, one TM_z and one TE_z . The TM_z leaky wave determines the E -plane pattern, while the TE_z leaky wave determines the H -plane pattern.⁸⁴ For a broadside beam these two leaky waves have very nearly the same phase and attenuation constants, and hence an omnidirectional pencil beam is created. Interestingly, this is true even if the PRS is not similar in the E - and H -plane directions. For example, the PRS may consist of a periodic array of slots in a metal plate, with the slots being long in the x direction and narrow in the y direction, having very different periodicities in the two directions. As the scan angle increases, the pencil beam turns into a conical beam, similar to how the petals on a flower unfold. As the scan angle increases (by increasing the frequency or the layer thickness) the wavenumbers of the two leaky waves typically begin to differ, and this explains why the beamwidths often become different in the principal planes. (The exact nature of the beamwidth variation with scan angle depends on the particular type of PRS.)

The PRS is used to create a leaky parallel-plate waveguide region, and the leaky waves are leaky (radiating) versions of the parallel-plate waveguide modes that would be excited by the source in an ideal parallel-plate waveguide, which results if the PRS is replaced by a perfectly conducting metal plate. This point of view allows for a simple design formula for the thickness of the dielectric layer in order to obtain a beam at a desired angle θ_0 (either a broadside or a conical beam). The parallel-plate waveguide modes are described by $n = 1$, meaning that there is one half-wavelength variation vertically inside the parallel-plate waveguide. (Although larger values of n could be used, this would result in a design that has a thicker dielectric layer.) The radial wavenumber of the TM_z and TE_z parallel-plate waveguide modes for an ideal waveguide would be

$$k_\rho = \beta = \sqrt{k_1^2 - \left(\frac{\pi}{h}\right)^2} \quad (11-43)$$

where h is the thickness of the dielectric layer and k_1 is the wavenumber of the layer, which may also be expressed as $k_1 = k_0 n_1$, where n_1 is the refractive index of the layer. Using the simple relation $\beta = k_0 \sin \theta_0$ that is valid for any leaky wave, we obtain the result

$$h = \frac{\lambda_0 / 2}{\sqrt{n_1^2 - \sin^2 \theta_0}} \quad (11-44)$$

The location of the source usually has little effect on the pattern shape, since this is dictated by the leaky-wave phase and attenuation constants. The phase constant is primarily determined by the thickness of the dielectric layer (see Eq. 11-43), while the attenuation constant is primarily determined by the properties of the PRS. However, the power density at the peak of the beam will be maximum when a horizontal electric dipole source is placed in the middle of the dielectric layer, or a horizontal magnetic dipole is placed on the ground plane.

A vertical electric dipole source maximizes the peak power density when it is placed on the ground plane, while a vertical magnetic dipole source does so when it is placed in the middle of the layer. Changing the peak power density, and hence the overall power radiated by the source, directly affects the input resistance of the source.

The PRS may be either uniform (e.g., one or more dielectric layers) or periodic in one or two dimensions (e.g., an array of closely spaced wires, or a 2D array of slots in a metal plate). However, it is important to note that for the periodic PRS structures, the radiation still occurs via the fundamental parallel-plate waveguide modes, and not from a space harmonic of these modes. That is, the PRS acts as a quasi-uniform reflective surface, where the reflection coefficient of the fundamental parallel-plate wave determines the characteristics of the antenna. The physical principle of operation is thus as a quasi-uniform leaky-wave antenna, and not a periodic leaky-wave antenna that radiates from a space harmonic.

To our knowledge, the first use of a quasi-uniform PRS to improve the antenna gain was described by von Trentini⁸⁵ in 1956. A sketch of that structure was presented by the author and is repeated here as Figure 11-36, in which he placed a source at P on a ground plane and then located a PRS parallel to the ground plane a distance l in front of it. He views the performance in terms of multiple reflections between the ground plane and the PRS, and then derives an expression for the resonance condition that yields maximum radiated power at broadside. In this derivation, he assumes that the PRS consists of an array of closely spaced parallel conducting wires oriented parallel to the electric field. With this model, he calculated the radiation patterns for several sets of dimensions. He also built and measured several antennas based on this PRS, and on others, including one consisting of an array of closely spaced circular holes in a metal plate. The source employed was a rectangular waveguide aperture, and measurements were made at a wavelength of 3.2 cm. The measurements and calculations for the main lobe of the radiation pattern agreed well with each other.

An improved version of the von Trentini antenna has been developed recently by Feresidis and Vardaxoglou.⁸⁶ These authors followed the von Trentini ray theory analysis, assuming the structure to have infinite extent, and employed a feed consisting of a rectangular waveguide built into the ground plane. The new contribution, and the “optimization” to which they refer, applies to their PRS structure. They note that the antenna would have greater bandwidth if the phase of its PRS were to linearly increase with frequency, in effect compensating somewhat for the path length that the rays must traverse (or equivalently for the change in the electrical thickness of the dielectric layer—see Eq. 11-44). They therefore investigated PRSs loaded with several different elements, such as crossed dipoles, patches, rings, and square loops. They found that dipoles, or square or circular patches (or their complementary structures), particularly with close packing of the elements in the array, produced less of a variation of the beam with frequency. This slower variation was not found for crossed dipoles, square loops, and rings, even for close packing of these elements. They therefore chose to use arrays of closely spaced dipoles in their PRS.

FIGURE 11-36 A ray explanation for the PRS-based leaky-wave antenna, as originally introduced by von Trentini (after von Trentini⁸⁵ © IEEE 1990)

Dielectric-Layer PRS Structures

Printed-circuit antennas, such as microstrip antennas, have many advantages for conformal applications, but they have the major disadvantage of low gain. During 1984 and 1985, Alexopoulos and Jackson published a pair of papers^{87,88} showing that the gain could be enhanced significantly by placing a dielectric superstrate, or cover layer, over the original dielectric layer. By choosing the layer thicknesses and the dielectric constant values appropriately, a large gain can be obtained for radiation at any desired angle, in the form of a pencil beam at broadside or a conical beam pointing at an angle θ_0 . The first of these two papers showed that a properly designed two-layer (substrate/superstrate) structure could produce such beams. The later paper⁸⁸ by Jackson and Alexopoulos examined in greater detail the quantitative relationships between the radiation properties of the two-layer dielectric structure and the parameter values (dimensions and permittivities) of the structure. Neither paper recognized the gain enhancement effect as due to leaky modes, however. The substrate-superstrate geometry of the structure, identifying the various parameters, is shown in Figure 11-37. A horizontal electric dipole source is shown located in the substrate and is parallel to the ground plane and the dielectric interfaces.

The superstrate layer will act as an optimum reflecting surface when the thickness is chosen so that it is an odd multiple of one-quarter of a wavelength in the vertical direction. This corresponds to the condition

$$t = \frac{(2m-1)\lambda_0}{4\sqrt{n_2^2 - \sin^2 \theta_0}} \quad (11-45)$$

where m is a positive integer and n_2 is the refractive index of the superstrate. Using $m = 1$ gives the thinnest superstrate.

An important next step was to recognize that the two-layer structure can support *leaky waves*, and that the structure can be analyzed as a *leaky-wave antenna*. A detailed analysis appeared in 1988 in a paper by Jackson and Oliner,⁸⁹ in which it was established that the directive beams obtained in the two-layer dielectric substrate/superstrate structure are due to the excitation of leaky modes by the horizontal dipole within the substrate layer. The leaky modes travel radially outward from the source and are supported by the two-layer structure. In particular, it was verified that a TM_z leaky mode determines the E -plane pattern, while a TE_z leaky mode determines the H -plane pattern. The trajectory of these two leaky modes in the steepest-descent plane illuminated very clearly how the radiated beam, as a combination of these two leaky modes, behaves as a function of frequency. The leaky-mode approach, which automatically takes into account how the leaky modes decay as they travel away from the dipole source, also tells us how large the ground plane and layer structure must be to act as if it is effectively infinitely wide. The leaky-wave approach is the only one that furnishes such information.

FIGURE 11-37 The two-layer substrate/superstrate configuration (after Alexopoulos and Jackson⁸⁷ © IEEE 1984)

The directivity increases as the permittivity of the superstrate layer increases relative to that of the substrate layer, since the superstrate PRS then acts as a more reflective surface. Another way to increase the reflection from the PRS was proposed by Yang and Alexopoulos⁹⁰ in 1987, in which the single superstrate is replaced by a *periodic array of such superstrates*, as shown in Figure 11-38. In this structure the PRS consists of a stack of multiple superstrate layers, where the high-permittivity superstrate layers with parameters (ϵ_2, μ_2) are separated by low-permittivity spacer layers with parameters (ϵ_1, μ_1). The high-permittivity layers have thickness t chosen from Eq. 11-45, while the low-permittivity spacer layers have one-half the thickness of the bottom dielectric layer. By using the multiple superstrates, the bottom layer is further isolated from the free-space region above, and the radiated beam becomes even narrower. The directivity increases geometrically with the number of superstrate layers, and thus very directive beams may be obtained using modest values of superstrate permittivity, provided several superstrate layers are used. A leaky-wave explanation for the multiple-layer dielectric structure proposed by Yang and Alexopoulos was presented in 1993 by Jackson et al.⁹¹ Formulas were derived for the leakage constant as a function of the layer parameters and the number of superstrate layers.

A fundamentally different approach to analyzing the multiple-superstrate structure was published in 1999 by Thevenot et al.⁹² The structure is the same as the one seen in Figure 11-38, but for only two superstrate layers. The source is also a patch antenna rather than a dipole, and the low-permittivity region is air. But the main point here is that the *approach* and its associated *terminology* are novel and completely different. In the adopted approach, a periodic array of low/high permittivity superstrate layers, which serves as the cover for the bottom dielectric layer, operates as a *photonic-band-gap* (PBG) structure, meaning that it is in a stopband. According to the authors, the design procedure is to “open an extra mode inside the frequency gap by inserting a defect into the dielectric period. The directive antenna described in this section uses the defect mode of a photonic crystal to achieve electromagnetic radiation. The PBG material is used as a cover to enhance the gain of a usual patch antenna.” Theoretical calculations were made of the radiation patterns of the patch antenna with and without the presence of the PBG cover. With the cover present, the directivity increased from 8 to 20 dB. Calculations were also made using an FDTD code, and then compared with measurements taken on an antenna structure built using a cover consisting of two layers of alumina rods. The comparison was quite good.

FIGURE 11-38 The multiple superstrate configuration, in which an alternating stack of low- and high-permittivity layers is used to form the PRS (after Yang and Alexopoulos⁹⁰ © IEEE 1987)

Periodic PRS Structures

As noted earlier, the PRS may consist of a periodic structure that is periodic in one direction, such as an array of closely spaced wires (or more generally, a stack of wire layers). The PRS may also consist of a 2D periodic array of elements. As also mentioned, the original work of von Trentini consisted of such PRSs. Here we examine the radiation properties for two particular PRSs, one consisting of a periodic array of metal patches,⁹³ and the other the complement, namely a periodic array of rectangular apertures or slots in a metal plate.⁹⁴

The metal-patch PRS structure is shown in Figure 11-34*b*, while the slot-PRS structure is shown in Figure 11-34*c*. Both PRSs may be used to produce a broadside pencil beam when air is used as the dielectric. Figure 11-39 shows a typical set of patterns obtained with the patch-PRS structure, showing the H -plane pattern for a broadside beam and a conical beam at $\theta_0 = 45^\circ$. The E -plane patterns, not shown, are similar. For a conical beam pointing at an angle $\theta_0 > 0$, the beam angle θ_0 is limited to about 45° . This is because the thickness h of the air layer increases without limit as the angle θ_0 increases toward 90° , as seen from Eq. 11-44. As the thickness increases beyond one wavelength, the next higher-order set of TM_z and TE_z parallel-plate modes ($n = 2$) begin to propagate, and radiation from this set of leaky modes results in an undesirable secondary beam.

The limitation on the beam angle due to the higher-order parallel-plate modes may be overcome by using a dielectric layer with $\epsilon_r > 4/3$, which allows for the beam angle θ_0 to approach 90° before radiation from a secondary beam occurs.⁹³ However, when using a dielectric layer with the patch-PRS, it is observed that undesirable secondary beams arise from another source, namely from the -1 space harmonic of the (perturbed) TM_0 surface wave that is supported by the grounded dielectric layer (which is perturbed by the metal patches).⁹³ This problem is avoided when using the slot-PRS structure since the guiding structure is now a perturbed parallel-plate waveguide (perturbed by the apertures) rather than a perturbed grounded slab. A beam approaching 90° may be realized by using a slot-PRS structure with a dielectric layer.⁹⁴ However, as the beam angle increases, the E - and H -plane patterns become increasingly different, with the E -plane pattern broadening and the H -plane pattern narrowing.

FIGURE 11-39 H -plane radiation patterns (in dB) at 12 GHz for a broadside beam and a 45° conical beam, for the patch-PRS structure of Figure 11-34*b*. The patches have lengths (x -dimension) of 1.25 cm and widths (y -dimension) of 0.01 cm, with periodicities of 1.35 cm in the x direction and 0.3 cm in the y direction. The thickness of the dielectric layer is $h = 1.33$ cm ($0.534\lambda_0$) for the broadside beam and $h = 1.90$ cm ($0.761\lambda_0$) for the conical beam. The structure is excited by an x -directed infinitesimal horizontal electric dipole in the middle of the layer (after Zhao et al⁹³ © IEEE 2005).

Very recent work has shown that it is possible to overcome the problem of different beam behaviors in the E - and H -planes by the use of a wire PRS (an array of closely spaced conducting wires) together with a dielectric layer that is air or a low-permittivity material.⁹⁵ Evidently, this is because the characteristics of the wire PRS change with the angle θ_0 in a manner so as to compensate for the natural change in the different principal planes as the beam angle changes (see the discussion in the next subsection).

General Design Formulas

The far-field pattern of a PRS leaky-wave antenna structure may be calculated by reciprocity, in which the far field is determined by illuminating the structure with an incident plane wave and calculating the field at the source dipole location.⁹⁶ The plane-wave calculation may be carried out by using a simple transverse equivalent network (TEN) model, which is a transmission-line model that represents the field behavior in the plane-wave problem. The PRS is assumed to be lossless and infinitesimally thin in the vertical direction, and therefore it is represented as a shunt susceptance B_L . Based on this simple model, formulas may be derived for the *beamwidth* and *pattern bandwidth* in the E - and H -planes, in terms of B_L .⁹⁶ The pattern bandwidth is defined from the frequency range over which the power density radiated at the angle θ_0 changes by less than 3 dB from the maximum value obtained at the center frequency (for which the structure is designed to radiate at angle θ_0).

Table 11-1 shows the beamwidth in the E - and H -planes for three separate cases: (1) broadside ($\theta_0 = 0^\circ$), (2) a general beam angle $0 < \theta_0 < 90^\circ$, and (3) end fire ($\theta_0 = 90^\circ$). The formulas are expressed in terms of the normalized shunt susceptance $\bar{B}_L = B_L \eta_0$, where η_0 is the intrinsic impedance of free space. It is seen that the beamwidths are equal at broadside, consistent with the fact that the beam is nearly omnidirectional. However, as the beam angle increases, the H -plane pattern becomes narrower, while the E -plane pattern becomes broader. A narrow beam can be obtained at the horizon in the H -plane (at least in theory) but not in the E -plane. It is noted that the beamwidth is inversely proportional to B_L^2 for a nonzero beam angle, but inversely proportional to B_L for a broadside beam. This means that the PRS must be much closer to a perfect reflecting surface in order to obtain a very narrow beam at broadside, compared with a nonzero beam angle.

TABLE 11-1 Expressions for Beamwidth

	E -plane	H -plane
Broadside	$2\sqrt{\frac{2n_1^3}{\pi \bar{B}_L^2}}$	$2\sqrt{\frac{2n_1^3}{\pi \bar{B}_L^2}}$
General beam angle	$\frac{2n_1^2 \sqrt{n_1^2 - \sin^2 \theta_0}}{\pi \bar{B}_L^2 \sin \theta_0 \cos^2 \theta_0}$	$\frac{2(\sqrt{n_1^2 - \sin^2 \theta_0})^3}{\pi \bar{B}_L^2 \sin \theta_0}$
End fire	Narrow beam not possible	$\frac{2(\sqrt{n_1^2 - 1})^3}{\pi \bar{B}_L^2}$

An analysis shows that the pattern bandwidth in the E - and H -planes is inversely proportional to B_L^2 for both a broadside beam and a conical beam. This means that for the same beamwidth the broadside pattern will have a much smaller pattern bandwidth than the conical beam.

12.1 INTRODUCTION

Helical antennas consist of a single conductor or multiple conductors wound into a helical shape. Although a helix can radiate in many modes, the axial mode and the normal mode are the ones of general interest. The axial mode, the most commonly used mode, provides maximum radiation along the helix axis, which occurs when the helix circumference is of the order of one wavelength. The normal mode, which yields radiation broadside to the helix axis, occurs when the helix diameter is small with respect to a wavelength. Higher-order-radiation modes are also possible; for example when the helix dimensions exceed those required for the axial mode, a conical or multilobed pattern will result, as illustrated in Figure 12-1.

The basic concepts of a helix antenna were established by Kraus^{1,2} in 1947, and much of Kraus's early results were summarized by Harris.³ Generally, helical antennas are wound with a single conduction. However, a helix can be designed with bifilar,⁴ quadrifilar,^{5,6} or multifilar⁷ windings. Radiation characteristics of bifilar helices operating in the backfire mode have been described by Patton.⁸ An advantage of a backfire helix is that it does not generally require a ground plane.

The helix-antenna parameters are defined as follows (see Figure 12-2):

D = diameter of helix (center to center)

C = circumference of helix = πD

S = spacing between turns (centers to center)

α = pitch angle = $\tan^{-1}(S/\pi D)$

N = number of turns

L = axial length of helix = NS

d = diameter of helix conductor

ℓ = length of one turn = $\sqrt{(\pi D)^2 + S^2}$

Although helical antennas are normally constructed with a circular cross section, elliptical helical antennas have also been investigated.⁹

This chapter presents detailed helical-antenna design information. Measured impedance, pattern, gain, and axial-ratio characteristics are shown for a variety of helical-antenna configurations. Empirical relations that express the antenna radiation performance characteristics as a function of wavelength and the helix design parameters (diameter, pitch angle, and number of turns) are derived on the basis of measured data.

FIGURE 12-2 Helix geometry

12.2 AXIAL-MODE HELICAL ANTENNAS

The helical beam antenna is a very simple structure possessing a number of interesting properties including wideband impedance characteristics and circularly polarized radiation. It requires a simple feed network, and its radiation characteristics are reasonably predictable. Either right-hand or left-hand circular polarization may be generated by a helical beam antenna. A helix wound like a right-hand screw radiates or receives right-hand circular polarization, while a helix wound like a left-hand screw radiates or receives left-hand circular polarization.

Helical antennas are generally constructed with a uniform diameter and operated in conjunction with a ground plane, cavity, or helical launcher.¹⁰ However, as will be shown, nonuniform-diameter helical structures can be employed to widen the bandwidth of a uniform-diameter helical antenna and to improve radiation performance characteristics.^{11,12}

A typical uniform-helix configuration is shown in Figure 12-3. The helix is backed by a circular cavity, rather than a conventional ground plane, to reduce the back radiation and enhance the forward gain. Although the helix of Figure 12-3 was designed¹¹ specifically to operate in the ultrahigh-frequency (UHF) range from about 650 to 1100 MHz, the helix and the cavity dimensions can be scaled to other frequencies of operation as well. The helix is fed by a coaxial connection at the bottom of the cavity. The helical conductor can be made from round tubing or flat strip and supported with a lightweight foam dielectric cylinder or by radial dielectric rods. The center mechanical support can be constructed from either metal or dielectric material.

Impedance and VSWR

The impedance characteristics of a helical antenna have been established by Glasser and Kraus.¹³ When the helix circumference is less than two-thirds wavelength, the terminal impedance is highly sensitive to frequency changes. However, when the circumference is of the order of one wavelength (axial mode), the terminal impedance is nearly a pure resistance and is given approximately (within ± 20 percent) by the empirical relation $R = 140 C/\lambda \Omega$. The relatively constant terminal impedance may be explained by the rapidly attenuating character of the total outgoing wave near the input end and the total reflected wave near the open end.¹⁴

For the UHF helix configuration of Figure 12-3, a 4.7-in- (119-mm-) long, linear-taper impedance transformer is used to match the 140- Ω helix to the 50- Ω coaxial line. The transformer is a microstripline constructed from Teflon-fiberglass printed-circuit board. The same transformer can be used for all axial-mode helices—uniform-, tapered-, or nonuniform-diameter. Another approach to attain a 50- Ω impedance for helical beam antennas has been described by Kraus.¹⁵

Figure 12-4 depicts the impedance characteristics of a five-turn helix with and without the impedance-matching transformer, and Figure 12-5 depicts the voltage-standing-wave-ratio (VSWR) response measured at the input of the matching transformer for a seven-turn uniform helix and also for the same helix with two additional turns of tapered diameter, as illustrated by the inset. By adding the two-turn end taper, a significant reduction in VSWR over a wide frequency

FIGURE 12-3 Mechanical arrangement of a cavity-backed helix for 650 to 1100 MHz

FIGURE 12-4 Impedance characteristics of a five-turn helix with and without an impedance-matching transformer

band can be achieved (dashed curve). The reduction in VSWR is due to the suppression of the reflected currents by the tapered end section.^{16,17} Also, it is noted that the low-frequency characteristics are essentially unchanged with the cutoff at ~ 534 MHz, corresponding to $C/\lambda \sim 0.75$, where C is the circumference of the 5.28-in- (134.1-mm-) diameter helix. The low-frequency cutoff characteristics agree well with theoretical predictions.^{1,2} The VSWR characteristics for longer helices are generally similar to those of Figure 12-5.

Uniform-Diameter Helices

As a first approximation, the radiation pattern of an axial-mode helix may be obtained by assuming a single traveling wave of uniform amplitude along the conductor. By the principle

FIGURE 12-5 VSWR of a seven-turn uniform helix and the same helix with two additional turns wound on a tapered diameter

of pattern multiplication, the far-field pattern is the product of the pattern of one turn and the pattern of an array of N isotropic elements with spacing S , where N equals the number of turns and S is the spacing between turns. If the pattern of a single turn is approximated by $\cos \theta$, where θ is the angle measured from the axis of the helix, the total radiation pattern becomes

$$E(\theta) = A \frac{\sin(N\psi/2)}{\sin(\psi/2)} \cos \theta \quad (12-1)$$

where

A = normalization factor

$$\psi = \frac{2\pi}{\lambda} S \cos \theta - \delta \quad (12-2)$$

$\delta = \frac{2\pi}{\lambda} \frac{\ell}{v/c}$ = progressive phase between turns

ℓ = length of one turn

v = phase velocity along helical conductor

c = velocity of light in free space

Kraus² has shown that for an axial-mode helix the relative phase velocity, $p = v/c$, of the wave propagating along the helical conductor is in close agreement with that required to satisfy the Hansen-Woodyard condition for an end-fire array with increased directivity¹⁸; i.e.,

$$p = \frac{(\ell / \lambda)}{(S / \lambda) + (2N + 1) / 2N} \quad (12-3)$$

Thus, for the increased-directivity condition, the quantity ψ may be written as

$$\psi = \frac{2\pi}{\lambda} S (\cos \theta - 1) - \frac{\pi}{N} \quad (12-4)$$

and

$$A = \sin(\pi / 2N) \quad (12-5)$$

The radiation is elliptically polarized. The ellipticity ratio or axial ratio (AR) of an N -turn helix operating in the axial mode for the increased-directivity condition is given by

$$\text{AR} = \frac{2N + 1}{2N} \quad (12-6)$$

If N is large, the axial ratio approaches unity and the polarization is nearly circular. In a practical situation, the observed axial ratio may be expected to deviate somewhat from the theoretical value for various reasons such as methods of construction, tolerances, instrumentation, and range errors. For a uniform helix consisting of at least a few turns, an axial ratio of the order of 1 dB is not uncommon.

To provide parametric design equations for axial-mode helices, Kraus² has suggested the following relations for the half-power beamwidth (HPBW) and gain (G) as a function of C/λ and NS/λ for constant-pitch helices with $12^\circ < \alpha < 15^\circ$, $3/4 < C/\lambda < 4/3$, and $N > 3$:

$$\text{HPBW} = K_B / (C / \lambda) \sqrt{NS / \lambda} \quad (12-7)$$

$$G = K_G (C / \lambda)^2 (NS / \lambda) \quad (12-8)$$

where K_B is the HPBW factor, K_G is the gain factor, $C = \pi D$ is the circumference, and NS is the axial length. On the basis of a number of pattern measurements on helices < 10 turns, Kraus quasi-empirically established $K_B = 52$. Also, he derived $K_G = 15$ for the directive gain (lossless antenna) based on the approximation $G = 41,250/(\text{HPBW})^2$, where HPBW is in degrees.

A gain-beamwidth product $G(\text{HPBW})^2 < 41,250$ is generally expected for most practical antennas¹⁹ because of minor-lobe radiation and beam-shape variations.

Additional data on the radiation characteristics of axial-mode helices are available in the literature.^{11,20-22} The low-frequency and high-frequency limits were investigated by Maclean and Kouyoumjian²⁰ and by Maclean.²³ In a practical situation, the pattern and gain versus frequency characteristics are of interest to the antenna designer. Such data would allow the designer to optimize the helix parameter for operation over a specified bandwidth.

The discussions that follow summarize the results of an extensive study of the gain and pattern characteristics of uniform helical antennas, one or eight wavelengths long, in the UHF range from about 650 to 1100 MHz. With reference to Figure 12-3, the helices were constructed by winding $\frac{3}{16}$ -in-diameter copper tubing about a Styrofoam cylindrical form that was concentric with 1.125-in-diameter metallic support tube. The helix dimensions can be scaled to other frequencies of operation with essentially the same radio-frequency performance characteristics. All gain and pattern measurements were made with respect to the phase center of the helix, which was estimated to be one-fourth of the helix length from the feed point.²⁴

Fixed-Length Helices Figures 12-6 and 12-7 show the gain and HPBW versus frequency characteristics, respectively, of a 30-in- (762-mm-) long ($NS = 30$ in) and 4.3-in- (109.22-mm-) diameter helix for three helix pitch angles ($\alpha = 12.5^\circ, 13.5^\circ$, and 14.5°). The helix with a smaller pitch angle (more turns per unit length) yields a higher peak gain and a lower cutoff frequency. With $N = 8.6$ to 10 turns, it appears that the gain-frequency slope is approximately proportional to f^3 and the HPBW-frequency slope is approximately proportional to $f^{-3/2}$, where f equals the frequency, which are in general agreement with Kraus for $C/\lambda < 1.1$ (see Eqs. 12-7 and 12-8). However, as will be shown later, experimental data indicate that the gain-frequency slope depends on the antenna length and is approximately proportional to $f\sqrt{N}$.

FIGURE 12-6 Gain versus frequency of a fixed-length ($NS = 30$ in, or 762 mm) helix; $\alpha = 12.5^\circ, 13.5^\circ$, and 14.5° , $D = 4.3$ in (109 mm)

FIGURE 12-7 Half-power beamwidth versus frequency of a fixed-length helix ($NS = 30$ in, or 762 mm); $\alpha = 12.5^\circ, 13.5^\circ$, and 14.5° , $D = 4.3$ in (109 mm)

FIGURE 12-8 Gain of a fixed-length ($NS = 30$ in, or 762 mm) helical antenna with different diameters

FIGURE 12-9 Half-power beamwidths of a 10-turn fixed-length ($NS = 30$ in, or 762 mm) helix with different diameters

Figures 12-8 and 12-9 show the gain and HPBW characteristics, respectively, of a 30-in-long ($N \approx 10$ turns) helix with variable diameter and pitch angle. The peak gain varies by less than 0.5 dB. In general, a slightly higher peak gain is observed for a larger-diameter helix with a smaller pitch angle, but the bandwidth is narrower than that of a smaller-diameter helix with a larger pitch angle.

The axial ratio, a measure of the purity of the circularly polarized wave, is generally less than 1.5 dB for $0.8 < C/\lambda < 1.2$. The axial ratio can be improved by tapering the last two turns of the helix, particularly at the high end of the band.^{12,17,25}

Variable-Length Helices Figures 12-10 and 12-11 show the gain and HPBW versus frequency, respectively, of helices consisting of 5 to 35 turns with constant pitch ($\alpha = 12.8^\circ$, $S = 3.03$ in, or 76.96 mm) and constant diameter ($D = 4.23$ in, or 107.4 mm). These helices were designed to operate over the UHF test frequencies with the helix circumference varied from 0.75λ to 1.25λ . N was selected as 5, 10, 12, 15, 18, 22, 26, 30, and 35 turns. The gain is referred to as a circularly polarized illuminating source. The gain curves reveal that the peak gain occurs at $C/\lambda = 1.55$ for $N = 5$ and at a lower value, $C/\lambda = 1.07$, for $N = 35$. The gain-frequency slope is not proportional to f^3 for all values of N (see Eq. 12-8); e.g., for $N = 5$ the gain varies approximately as $f^{2.5}$, and for $N = 35$ the gain follows approximately an f^6 slope, where f is the frequency.

FIGURE 12-10 Gain versus frequency for a 5- to 35-turn helix; $\alpha = 12.8^\circ$, $D = 4.23$ in (107.4 mm)

FIGURE 12-11 Half-power beamwidths versus frequency for a 5- to 35-turn helix; $\alpha = 12.8^\circ$, $D = 4.23$ in (107.4 mm)

Typical measured radiation patterns for $N = 5, 10, 18$, and 35 are shown in Figure 12-12. The axial ratio is ~ 1 dB over most of the measurement frequency range and is slightly higher at the band edges. The HPBW's are generally within $\pm 1^\circ$ in the two orthogonal principal planes. At frequencies a few percent above the peak gain frequency, the patterns begin to deteriorate. The beamwidth broadens rapidly, and the first sidelobes merge with the main lobe as the operating frequency approaches the upper limit.

Parametric helix characteristic curves—gain and halfpower beamwidth—for the 4.23-in- (107.4-mm-) diameter constant-pitch ($\alpha = 12.8^\circ$) helix are shown in Figures 12-13 and 12-14, respectively, as a function of axial length NS/λ with circumference $\pi D/\lambda$ as a parameter. Thus, for a specified length and diameter, the helix gain and HPBW can be estimated.

Figure 12-15 depicts the gain-beamwidth product $K = G (\text{HPBW})^2$ based on the measured gain data of Figure 12-10 and the HPBW data of Figure 12-11. The quantity K is useful for estimating the gain when the HPBW is known, and vice versa. It should be noted, however, that the gain-beamwidth product is not constant but depends on N and frequency. All curves have been smoothed to within ± 5 percent of the measured-data points.

Empirical Relations On the basis of the gain data of Figures 12-6, 12-8, and 12-10, the peak gain may be empirically expressed as¹¹

$$G_p = 8.3 \left(\frac{\pi D}{\lambda_p} \right)^{\sqrt{N+2}-1} \left(\frac{NS}{\lambda_p} \right)^{0.8} \left[\frac{\tan 12.5^\circ}{\tan \alpha} \right]^{\sqrt{N}/2} \quad (12-9)$$

FIGURE 12-12 Typical radiation patterns of a 5- to 35-turn helix; $\alpha = 12.8^\circ$, $D = 4.23$ in (107.4 mm)

FIGURE 12-13 Parametric helix-antenna gain curves as a function of axial length with circumference as a parameter

where λ_p is the wavelength at peak gain. The computed values for the fixed-length helices ($NS = \text{constant}$) are within ± 0.1 dB of the measured data, as depicted in Figure 12-16. The data points indicated by the circle were obtained by varying the diameter and pitch angle while keeping the length constant with $N = 10$ turns, and those indicated by the triangle were obtained by varying the pitch angle while keeping the length and diameter constant ($N \approx 8.6$ to 10). The diameters of the various experimental helices are shown on the top of the figure. For the fixed-length helices, the peak gains occur at nearly the same circumference, $\pi D/\lambda \sim 1.135$.

Figure 12-17 is a plot of the peak gain versus N for a constant-pitch ($\alpha = 12.8^\circ$) helix. The corresponding values of C/λ_p are also shown in the figure, where λ_p is the wavelength at peak gain. The peak gain is not quite proportional to the number of turns; i.e., doubling the number of turns does not yield a 3-dB increase in the peak gain. The computed values for the peak gain, using Eq. 12-9 with $\alpha = 12.8^\circ$ and $N = 5$ to 35 turns, are within ± 0.1 dB of the measured data.

FIGURE 12-14 Parametric helix-antenna half-power-beamwidth curves as a function of axial length with circumference as a parameter

FIGURE 12-15 Gain-beamwidth products of a 5- to 35-turn helix; $\alpha = 12.8^\circ$, $D = 4.23$ in (107.4 mm)

FIGURE 12-16 Peak gain of a fixed-length helix ($NS = 30$ in, or 762 mm) as a function of a pitch angle

A similar empirical expression for the HPBW is as follows:²⁶

$$\text{HPBW} \approx \frac{K_B \left(\frac{2N}{N+5} \right)^{0.6}}{\left(\frac{\pi D}{\lambda} \right)^{\sqrt{N}/4} \left(\frac{NS}{A} \right)^{0.7}} \left(\frac{\tan \alpha}{\tan 12.5^\circ} \right)^{\sqrt{N}/4} \quad (12-10)$$

where K_B is a constant in degrees. For the helices constructed by using the arrangement of Figure 12-3, it was found that, with $K_B \approx 61.5^\circ$, Eq. 12-10 matches the measured data within \pm a few percent over the useful operating frequency range of the helix, as shown in Figures 12-7, 12-9, and 12-11. For helices that employ a different construction technique (e.g., tape helices that are wound on a dielectric support instead of using a metallic central support rod), Eq. 12-10 can still be applied, but a slightly different value of K_B must be used. The measured HPBWs for the helices investigated are generally 10 to 20 percent

FIGURE 12-17 Peak gain of a variable-length helix with $\alpha = 12.8^\circ$

FIGURE 12-18 Gain-bandwidth characteristics of a uniform helix with $\alpha = 12.8^\circ$

wider than Kraus's formula (see Eq. 12-7). It should be mentioned that Eqs. 12-9 and 12-10 are not unique; however, these relations are useful as a design tool.

The helix bandwidth may be defined as the operating frequency range over which the gain drops by an allowable amount. The -3-dB and -2-dB bandwidths as a function of N may be obtained by using the curves of Figure 12-18. For example, if the -3-dB or -2-dB bandwidth is desired for a given N , you determine the values of $\pi D/\lambda_h$ and $\pi D/\lambda_\ell$ from Figure 12-18, where λ_h and λ_ℓ are the free-space wavelengths corresponding to the upper frequency limit f_h and the lower frequency limit f_ℓ , respectively. The choice of a -3-dB or -2-dB bandwidth depends upon the antenna designer's application. The frequency limits f_h and f_ℓ may be determined by using the measured gain data of Figure 12-10. Note that the gain varies approximately as $f^{\sqrt{N}}$ for $f < f_p/1.04$ and as $f^{-3\sqrt{N}}$ for $f > 1.03f_p$, where f_p is the frequency at peak gain. On the basis of these observations, the bandwidth frequency ratio may be empirically expressed as¹¹

$$\frac{f_h}{f_\ell} \approx 1.07 \left(\frac{0.91}{G/G_p} \right)^{4/(3\sqrt{N})} \quad (12-11)$$

where G_p is the peak gain from Eq. 12-9. The computed bandwidth characteristics for $G/G_p = -3 \text{ dB}$ and -2 dB agree reasonably well with the measured data as shown in Figure 12-18. The bandwidth decreases as the axial length of the helix increases. This bandwidth behavior follows the same trends described by Maclean and Kouyoumjian,²⁰ although these authors employ a sidelobe criterion rather than a gain criterion. Beyond the $G/G_p = -3 \text{ dB}$ point, the gain drops off sharply at the high-frequency end as the upper limit for the axial mode is approached.

Nonuniform-Diameter and Tapered Helices

The tapered-diameter^{27,28} and nonuniform-diameter¹² helices represent additional types of axial mode helical antennas. These helical configurations are capable of providing a wider bandwidth than a conventional uniform (constant-diameter) helix. A nonuniform helix

FIGURE 12-19 Various axial-mode helical configurations

consists of multiple uniform-diameter helical sections that are joined together by short tapered transitions. Some studies have been made to investigate the broadband-frequency response of nonuniform-diameter helical antennas.^{29,30} The various types of helical-antenna configurations (uniform, tapered, and nonuniform-diameter) are shown in Figure 12-19, and the radiation performance characteristics are described in Wong and King.¹²

The experimental helices were wound with thin copper strips 0.468 in (11.887 mm) wide. The plane of the strip (the wide dimensions of the strip) was wound orthogonally to the helix axis similarly to a Slinky toy. Helices wound with round conductors or with metallic tapes (wound so that the plane of the tape is parallel to the helix axis) yield similar results. A constant-pitch spacing of 3.2 in (81.28 mm) was selected, and the helix was backed by an 11.25-in- (285.75-mm-) diameter \times 3.75-in- (95.25-mm-) high cavity. The feed arrangement and the metallic central support tube are similar to those of Figure 12-3. The VSWR of a nonuniform helix is $\leq 1.5:1$ over the test frequency range of 650 to 1100 MHz (similar to the dashed curve of Figure 12-5).

Tapered-End Helices For reference purposes, the gain and axial-ratio characteristics of an 18-turn uniformly wound helix, with $D = 4.59$ in (116.59 mm) and $\alpha = 12.5^\circ$, are shown in Figure 12-20. Also shown in this figure are the gain and axial-ratio characteristics of a similar helix with the same overall length, but the diameter of the last two turns is tapered from 4.59 in to 2.98 in (75.69 mm). It can be seen that the end taper provides a marked improvement in axial-ratio characteristics,^{12,16,17} although the peak gain is reduced slightly. Figure 12-21 compares the radiation patterns of a uniform and a tapered-end helix measured at the same frequency. The HPBW's are approximately the same, but the axial-ratio improvement is observed over the entire pattern (on axis and off axis). Similar results have been reported by Donn.²⁵

Continuously Tapered Helices The gain and axial characteristics of a continuously tapered helix,¹² often referred to as a *conical helix*, are shown in Figure 12-22. The helix consists of 17.64 turns with a constant-pitch spacing of

FIGURE 12-20 Gain and axial-ratio characteristics of an 18-turn uniformly wound and tapered-end helix

FIGURE 12-21 Radiation patterns of an 18-turn (a) uniform and (b) tapered-end helix

3.2 in (81.28 mm) and tapers from a 5.32-in (135.12-mm) diameter at the base to a 2.98-in (75.69-mm) diameter at the top (see inset). Typical measured patterns are shown in Figure 12-23. The peak gain is slightly lower than that of the uniform helix, but the pattern characteristics and bandwidth performance are much better.

Nonuniform-Diameter Helix A nonuniform helix provides a unique approach for widening the bandwidth of a helical antenna with improved gain and pattern characteristics. It may be constructed with two or more uniform helix sections of different diameters or a combination of uniform and tapered sections. The dimensions of the different helical sections (diameter, number of turns, etc.) can be varied to synthesize an antenna with a specific gain-frequency response.^{12,31}

FIGURE 12-22 Gain and axial-ratio characteristics of a 17.64-turn conical helix

FIGURE 12-23 Radiation patterns of a 17.64-turn conical helix

Two nonuniform helical configurations and the corresponding gain and axial-ratio characteristics are illustrated in Figure 12-24. Configuration *a* consists principally of two uniform-diameter sections [5.28 and 4.13 in (134.1 and 104.9 mm)] joined together by a short tapered transition. This helix may be described as 7-turn (5.28 D) + 2-turn taper (5.28 D to 4.13 D) + 6.64-turn (4.13 D) to 2.98 D). A constant-pitch spacing of 3.2 in (81.28 mm) was maintained in all four helical sections. The performance of this nonuniform helix configuration was optimized over the low-frequency region. The gain is 14.7 ± 0.4 dB from 773 to 900 MHz and remains relatively flat (14.05 ± 0.25 dB) from 900 to 1067 MHz. Note that the gain is constant within ± 1 dB over a frequency ratio of 1.55:1 (1100/710 MHz) as compared with 1.26:1 for a uniform helix. Table 12-1 provides a comparison of the ± 1 -dB bandwidth for the various axial-mode helical antennas. The axial ratio is < 1 dB. The beam-shape and sidelobe characteristics are improved over those of a uniform helix, as illustrated in the patterns of Figure 12-25. Note that the high-frequency cut-off is limited not by the larger 5.28-in-diameter helical section ($C/\lambda = 1.55$ at 1100 MHz) but rather by the smaller 4.12-in-diameter helical section ($C/\lambda = 1.21$ at 1100 MHz). The HPBW is relatively constant, $33^\circ \pm 3^\circ$ over the 773- to 1067-MHz test frequency range.¹²

Configuration *b* of Figure 12-24 consists of a uniform section (5.28-in diameter) plus a tapered section from 5.28- to 2.98-in diameter. The ± 1.1 -dB gain bandwidth is wider than that of configuration *a*, but the gain at the high-frequency end is lower.

FIGURE 12-24 Gain and axial-ratio characteristics of two 17.64-turn nonuniform-diameter helices

TABLE 12-1

Type of Helix	Frequency Range with ± 1 -dB Gain Variation, MHz	Frequency Ratio, f_{\max}/f_{\min}
Uniform	770–970	1.26:1
Tapered-end	770–980	1.27:1
Continuous-taper	820–1120	1.37:1
Nonuniform	710–1100	1.55:1

12.3 ARRAY OF HELICAL ANTENNAS

A single axial-mode helical antenna produces moderate gain in the end-fire direction (see Figure 12-17). When higher gain is desired, a linear or planar array of helices may be used to produce a fan-shaped beam or a pencil beam, respectively. The array gain depends on the element spacing with respect to the operating wavelength and the element gain. To realize the advantage of the increased gain, the helical elements should be spaced so that the area occupied by each helix is approximately equal to its effective area. To the first-order estimate, this spacing is $\sim \sqrt{G_e / 4\pi\lambda}$, where G_e is the power gain of the individual helices. As the spacing is increased to $> \sqrt{G_e / 4\pi\lambda}$, the array gain approaches the asymptotic value NG_e , where N is the number of elements.³² Some measured data on this type of array have been reported by Harris,^{3,33} and the construction and the radiation characteristics of a typical 2×2 planar array of six-turn helices ($D = 0.3\lambda$ and $\alpha = 14^\circ$) spaced 1.5λ are shown in Figures 12-26 and 12-27, respectively. Also, shaped-beam and steerable arrays employing axial-mode helices have been designed for spacecraft applications.^{22,34,35}

Generally, arrays employing high-gain elements are not suitable for wide-angle scanning because of grating lobes. However, when antenna gain and side-lobes (or grating lobes) are not important, such arrays can be phased to scan over a limited angular range.

For certain applications, such as FM and TV broadcasting, a moderately high-gain, azimuthally omnidirectional pattern is required. A vertical array of side-fire helices mounted concentrically on a conducting cylinder may be employed to produce a narrow-beam pattern in the elevation plane. The helix elements are generally excited in the second- or higher-order modes that produce maximum radiation broadside (normal) to the helix axis and a null along the helix axis. The helix diameter and pitch are chosen so that the length of one turn is equal to an integral number of wavelengths.

FIGURE 12-25 Radiation patterns of a 17.64-turn nonuniform-diameter helix—configuration *a* of Figure 12-24

FIGURE 12-26 2×2 array of six-turn helices

If horizontal polarization is desired, the radiating element may be constructed with two oppositely wound helices (one right-handed and the other left-handed), each consisting of a few turns, placed end to end and fed in the center. Design data on this type of vertical array are available in the literature.^{3,36,37}

Vertical helical-array antennas designed to produce omnidirectional, circularly polarized radiation in the horizontal plane for VHF-UHF TV broadcasting have been described by DuHamel.³⁸ In this case, the radiating elements are end-fed, four-turn bifilar helices operating in various modes that are selected so that the helix circumference is about $\lambda/2$ greater than the circumference of the central support cylinder. Depending on the operating frequency, horizontal circularity of ± 0.5 dB to ± 1 dB and an axial ratio of ~ 1.5 dB have been reported.

FIGURE 12-27 Measured characteristics of a 2×2 array of six-turn helices

12.4 NORMAL-MODE HELICAL ANTENNAS

When the dimensions of the helix are small compared with the wavelength, the maximum radiation is in a direction normal to the helix axis. Kraus² has shown that the radiation from a short-axial-length helix can be calculated by assuming that the helix is composed of small loops of diameter D and short dipoles of length S . The far field of a short dipole has only an E_θ component,

$$E_\theta = \frac{jBe^{-jkr}}{r} \left(\frac{S}{\lambda} \right) \sin \theta \quad (12-12)$$

and the far field of a small loop has only an E_ϕ component,

$$E_\phi = \frac{Be^{-jkr}}{2r} \left(\frac{\pi D}{\lambda} \right)^2 \sin \theta \quad (12-13)$$

where r is the distance and B is a constant. The E_θ and E_ϕ components are 90° out of phase, and the far field of a small helix is, in general, elliptically polarized. The axial ratio is given by

$$\text{AR} = \frac{|E_\theta|}{|E_\phi|} = \left(\frac{2S}{\lambda} \right) / \left(\frac{\pi D}{\lambda} \right)^2 \quad (12-14)$$

When $\pi D = \sqrt{2S\lambda}$, the axial ratio becomes unity and the radiation is circularly polarized.³⁹ On the other hand, the polarization of the radiated field will be predominantly horizontal ($\text{AR} \rightarrow 0$) when $\pi D \gg \sqrt{2S\lambda}$ or predominantly vertical ($\text{AR} \rightarrow \infty$) when $\pi D \ll \sqrt{2S\lambda}$.

For a normal-mode helix whose dimensions are small compared with wavelength, the current distribution along the helix is approximately sinusoidal.² The terminal impedance is very sensitive to changes in frequency, and the bandwidth is narrow. Nevertheless, a normal helix has been used effectively to reduce the length of thin-wire-type (whip) antennas for personal radio and mobile communications systems in the HF and VHF bands.⁴⁰⁻⁴³ Also, balanced-fed dipole antennas can be constructed by using short-axial-length normal-mode helices when a reduced dipole length is desired.⁴⁴

When a short normal-mode helix is used in conjunction with a ground plane, the polarization is predominantly vertical and the radiation pattern is similar to that of a monopole. The radiation resistance of a short resonant helix above a perfect ground is approximately given⁴⁰ by $(25.3 h/\lambda)^2$, where h is the axial length or height above the ground plane.

Typical feeding arrangements for a helical monopole are shown in Figure 12-28. In the series-fed arrangement, the helix is connected directly to the coaxial input, and an impedance transformer or matching network may be required. In the shunt-fed arrangement, the helix provides a self-matching network by tapping a small portion of the helix. A feed arrangement that employs a bifilar helix to increase the input impedance is described in Hansen,⁴¹ and another design that utilizes a short helical monopole and top-loading wire to produce a self-resonant antenna over the 2–30-MHz frequency range without the need of a matching device is described in Eovine.⁴³

FIGURE 12-28 Typical feed arrangements for a helical monopole

12.5 OTHER HELICAL ANTENNAS

Fractional-Turn Resonant Quadrifilar Helices A class of resonant quadrifilar helices, also referred to as *volute*s, capable of radiating circular polarization with a cardioid-shaped pattern has been described by Kilgus.⁴⁵⁻⁴⁷ The antenna consists of two orthogonal fractional-turn (one-fourth to one turn) bifilar helices excited in phase quadrature. Each bifilar helix is balun-fed at the top, and the helical arms are wires or metallic strips of resonant length ($\ell = m\lambda/4$, $m = 1, 2, 3, \dots$) wound on a small diameter with a large pitch angle. The ends of the helices are open-circuited at the base when $m = \text{odd}$ and short-circuited when $m = \text{even}$. When properly excited, the volute produces a very broad beamwidth with relatively low backlobes and good axial-ratio characteristics over a wide angular range. Since the volute is a resonant structure, the impedance bandwidth is narrow. Typically, the VSWR is $< 2:1$ over a 3 to 5 percent bandwidth. Generally a wider bandwidth can be achieved with larger-diameter wires for a given helix design. This type of antenna has been designed for various applications requiring a wide beamwidth over a relatively narrow frequency range.^{48,49}

Because of its low-backlobe characteristics, a volute can be operated as an isolated antenna or with a ground plane. A half-turn $\lambda/2$ -volute antenna and a typical measured pattern obtained with a rotating linearly polarized source at 488 MHz are shown in Figure 12-29.

FIGURE 12-29 Half-turn, half-wavelength volute antenna and measured pattern at 488 MHz

The pattern was measured with a 90° hybrid connected to the coaxial input ports of the two bifilar helices. The half-turn, half-wavelength volute is of particular interest because the input impedance of each bifilar can be matched to a 50- Ω coaxial input simply by minor adjustment of the helical-arm lengths without the need of a transformer. The measured VSWR is < 2:1 over ~5 percent bandwidth centered at 488 MHz.⁵⁰

Short Axial-Mode Helices For certain applications requiring a wideband and broadbeam antenna with a relatively small physical size, such as reflector feeds, a short axial-mode helix (two to four turns) housed in a conical or circular cavity similar to that of Figure 12-3 can be employed. As discussed in the subsection “Nonuniform-Diameter and Tapered Helices,” the end of the helix may be slightly tapered to improve the VSWR and axial-ratio performance. A similar cavity-backed short helix designed for flush-mounting applications is described by Bystrom and Berntsen.⁵¹ A dual-helix feed system that utilizes two concentric helices to provide operation over two narrow-frequency bands is described by Holland.⁵²

A helical feed design for a paraboloidal reflector that utilizes a four-turn backfire bifilar helix is described in King and Wong.⁵³ This feed was designed for a spacecraft antenna operating in the 240- to 270-MHz band.* An attractive feature of the backfire bifilar-helix feed is that it does not require a cavity or ground plane, thus minimizing blockage effects and improving reflector-antenna efficiency. Based on the measured gain results reported in King and Wong,⁵³ antenna efficiency of 64 to 70 percent is achievable over a 12 percent bandwidth. Similar reflector feed designs employing a backfire monofilar helix have been described by Johnson and Cotton⁵⁴ and Nakano et al.⁵⁵

Short-axial-mode helices with less than three turns are useful for array applications, particularly when circular polarization is desired. Nakano et al.⁵⁶ have demonstrated that a two-turn helix with a pitch angle as small as 4° can provide an axial ratio of less than 3 dB over a 12 percent bandwidth. A combination of low pitch and a small number of turns results in a low-profile configuration. A circular array using the two-turn helix as the radiating element is described in Nakano et al.⁵⁷

The performance of a short-axial-mode helix is generally limited by its axial ratio and bandwidth characteristics. The helix can be designed to operate over a larger bandwidth if a larger pitch angle is employed and with some compromise on the minimum achievable axial ratio. Figure 12-30 depicts the typical measured radiation patterns of a 1.59-turn helix with a pitch angle of 11° on a 30- by 30-in (76.2- by 76.2-cm) ground plane.† The axial ratio varies from 1 to 3 dB in the 1.8- to 2.4-GHz band, which represents a bandwidth of nearly 30 percent. The helix was constructed using 0.081-in (2.06-mm) diameter copper wire wound on a Styrofoam cylinder. Additional laboratory experiments indicated that the axial ratio characteristics of short-axial-length helices can be improved by loading the helix end with a small taper, a small loop, or a flat spiral.

As mentioned previously, when a short-axial-mode helix is used as a single widebeam element, it can be placed in a circular cavity instead of a ground plane. Limited laboratory measurements showed that there are no significant changes in axial ratio characteristics. Also, when a short-axial-mode helix with an imperfect axial ratio is used as the radiating element for an array, the overall axial ratio characteristics of the array can be improved by

*By TRW Systems Group, Redondo Beach, Calif.

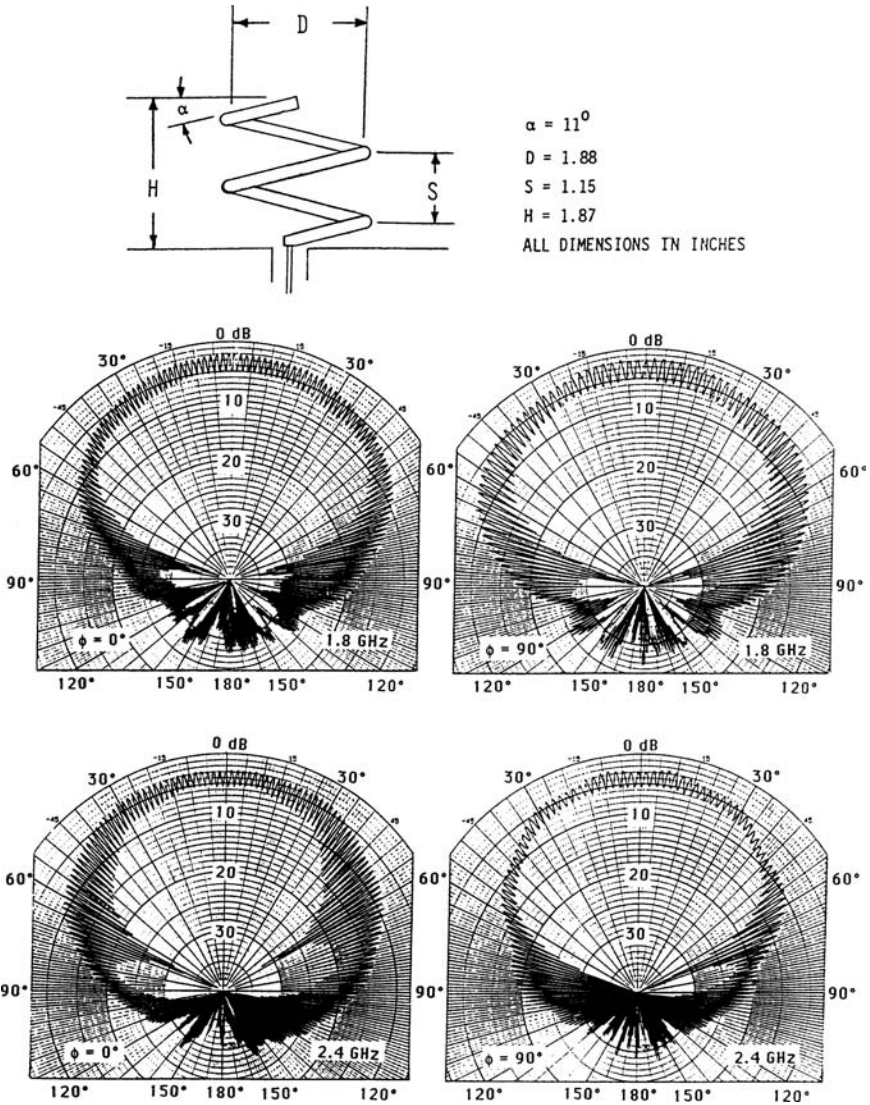

FIGURE 12-30 Radiation patterns of a 1.59-turn helix on a 30- by 30-in ground plane

appropriately arranging the relative orientation (roll position) and adjusting the excitation phase of the individual elements within the array.⁵⁸

Helicone Antennas An axial-mode helix can be operated in conjunction with a conical horn to provide a broadband antenna with low sidelobes.⁵⁹ The axial length of the helix and the horn are approximately the same. Sidelobe levels of the order of -25 dB have been reported. Design and performance data are available in the literature.⁶⁰

FIGURE 12-31 SKYNET 4 UK MOD spacecraft UHF helical antenna designed and built in 1984 by Sultan et al^{61–63} at CAL (Canadian Astronautics Limited—now EMS Technologies Ottawa). Similar antennas were later deployed on NATO and The National Reconnaissance Office. GeoLITE satellite built by TRW/NRO, <http://spaceflightnow.com/delta/d285/010517geolite.html>. Posted May 17, 2001.

12.6 SATELLITE WIDEBAND HELICAL ANTENNA DESIGN

For space applications the optimization of mass, size, and gain of the antenna are essential. In addition, spacecraft such as SKYNET, NATO, and GeoLITE require, at launch, a stowed tapered helical antenna that is deployable on-orbit, by extending a center rod and using a metal tape as radiating elements. Canadian Astronautics Ltd.^{61–63} built and tested a wide range of single and multisection, single and multipitch uniform cylindrical and tapered helices. To achieve wide bandwidth, stepped cylindrical⁶¹ instead of tapered helical antennas were proposed with multisections and multipitch angles. One of the resulting configurations was a pair of concentric helices sharing the same ground reflector. This 2-wavelength-long antenna provides 12-dBi gain at 760 and 1290 MHz, with 16 dB isolation between the frequencies to reduce passive intermodulation.

To date, there are no simple mathematical solutions for designing helical antennas. Unfortunately, a 1-dBi uncertainty can lead to as much as one-third of the helix length. Most often, modeling software based on NEC⁶⁴ is used to compute the currents on the helix wire or metallic tapes forming the helix.

12.7 RECENT DEVELOPMENTS

Cardoso and Safaai-Jazi^{65–67} found that winding a helix on a spherical, rather than a cylindrical, surface can produce designs that maintain good circular polarization over a broader beamwidth. Hemispherical designs have also been proposed and have the advantage of reduced height and operation over a wide angular region.^{68–72} Various methods have been presented for reducing the size^{71–73} and improving the bandwidth of helical antennas,^{74–78} including the use of wideband impedance matching.^{79–81} Finally, it is worthy of note that in 1995, Kraus presented an axial mode helix design that did not require a ground plane.⁸²

13.1 INTRODUCTION

Theoretically, frequency independent (FI) antennas have near-field and far-field characteristics independent of frequency. Thus, an FI antenna must have an infinitely large aperture to eliminate the low-frequency limit. It must also have a very fine and infinitely small feed region to remove the high-frequency limit. To eliminate length-dependent scaling, an FI antenna is exclusively described by angles. To reduce and ideally eliminate the far-field contamination, the residual currents must decay to zero after passing through the active (principal or main) region and before entering the next-higher order radiating region. The complete radiation from a single active region, also known as constructive radiation, is however not possible. Finally, an ideal FI antenna must have a frequency independent feed.

Certainly, no practically realizable antenna can fulfill these requirements. Thus, realistic FI antennas are radiators having virtually invariant impedance and pattern characteristics over very wide instantaneous bandwidths or consecutive multiple logarithmically periodic bands. Consistent impedance and pattern characteristics over 100:1 bandwidths have been successfully demonstrated, so that the system bandwidth is commonly limited by the electronics, rather than by the antenna. Owing to the previously mentioned properties, FI antennas have become irreplaceable components of many, predominantly military, systems. This chapter outlines the fundamental principles of frequency independence and reviews many antenna structures belonging to this class.

Basic Principles

The following principles underline FI antennas and their performance¹⁻⁷:

- Geometry scaling
- Geometry description by angles
- Truncation of residual currents
- Self-complementarity

Clearly, these principles disregard effects of the balun feed, which must be frequency independent over the same finite bandwidth as the antenna. In a nondispersive medium, the current distribution on an FI antenna as a function of frequency remains fixed only if both the dimensions of the antenna and the operating wavelength are changed by the same fraction. This ensures that the antenna's electrical dimensions remain invariant to changes in operating frequency. Consequently, the invariance of currents (sources) with normalized frequency leads to near- and far-field invariance with frequency. This scaling concept can be readily extended for inhomogeneous structures composed of metals and dielectrics if all dimensions are scaled inversely proportional to frequency.

To obtain continuous scaling of antenna performance with frequency, the radiating structure of the antenna must be specified only by angles. This way the frequency scaling, which for antennas with a lineal structural form results in resonance scaling, corresponds to rotation and translation of the basic structure. Exact mathematical formulation for frequency independent planar and non-planar antennas, based on the previous principles, will be derived later in this section.

Theoretically, an infinitely broadband FI antenna, defined purely by angles, must be infinitely large with infinitely fine center details. However, for any practical use where the bandwidth of the system electronics and allowed space are finite, the antenna bandwidth may be reduced accordingly. To maintain the FI performance while having reduced/finite size,

the antenna must obey the truncation principle. That is, the residual currents must decay to zero after they have been radiated from the principal active region. By allowing significant existence of residual currents, impedance and pattern degradations can occur. Impedance bandwidth is affected when these currents reach antenna ends and reflect back to the feeder. This effect can be mitigated, as will be shown later. Pattern degradation occurs due to the radiation from the higher order regions when the antenna is large enough and from the residual currents reflected from the arm ends. However, if the residual currents decay to zero or to a very small value, then the antenna aperture can be terminated at the finite distance and reflection from the ends will be eliminated. This way, as the frequency is increased, the radiation pattern of a finite, truncated structure approaches limiting form; that is, the pattern of an infinite structure.

The truncation principle establishes the low-frequency limit of an FI antenna. At the lower end of operation, two important situations must be addressed. First, the high-frequency regions become part of the antenna feed system. More clearly, the low-frequency wave, while traveling to the designated active region, uses the path between the feed and active region as a transmission line. Second, at some frequency the currents will start to interact with the antenna ends before decaying to zero. Below this frequency, the antenna will still radiate, but its current distribution will be disturbed and antenna impedance and pattern will be inconsistent with frequency. To mitigate end effects, a lossy termination is typically integrated with the end of the radiator. The upper-frequency limit is determined by the precision with which the balun and feed region can be fabricated.

Self-complementarity is not a necessary condition for FI performance. This principle states that if the interchange of metallic and nonmetallic parts on a planar antenna embedded in a homogeneous medium leaves the geometry unchanged except for a rotation equal to one half of the angular periodicity, then the respective impedances of two complementary antennas are related by

$$Z_{\text{METAL}} Z_{\text{SLOT}} = \left(\frac{\eta}{2} \right)^2 \quad (13-1)$$

where η is the plane wave impedance for the homogeneous medium (for an antenna in air $\eta = 120\pi \Omega$, and the impedance is $Z_{\text{METAL}} = Z_{\text{SLOT}} = 188.5 \Omega$). Equation 13-1 is based on Booker's extension of Babinet's principle⁶ and has been widely utilized in designing antennas with a broadband impedance match. Self-complementary two-arm spiral, four-arm sinuous, and four-arm planar log-periodic antennas are shown in Figure 13-1.

FIGURE 13-1 Examples of self-complementary planar structures: (a) two-arm spiral, (b) four-arm sinuous, (c) and four-arm planar log-periodic

Antennas with minimum impedance and pattern variations over a frequency range repeated with the logarithmic periodicity also adhere to the FI principles. Both infinitely large and infinitesimally fine structure is needed to comply with the theoretical requirements; however, for practical purposes, these conditions are relaxed. The connection between the two apparently different FI conceptual approaches is mathematically well supported. Specifically, the conical screw FI antenna structure allows log-periodic antennas to become FI. Finally, note that this principle is more a rule for evaluation rather than for design, and it implies that a properly designed FI antenna should have identical performance at frequencies related by the (logarithmic) periodicity of the antenna with as little performance variation as possible within each period.

The two arms of a self-complementary six-arm log-periodic structure are depicted in Figure 13-2. The geometric ratio, or growth rate, is denoted by τ and is the ratio of frequencies between which *small* variations in antenna performance occur. The growth rate is also equal to the ratio of the lower (smaller) and the next higher (larger) repeatable structural dimension (i.e., $\tau = f_n / f_{n+1} = r_{n+1} / r_n$). To be able to truncate the log-periodic geometry, the antenna must be designed to eliminate radiation in the direction of the antenna's low-frequency expansion. If the pattern null is not produced in the truncated direction, the currents will also exist in infinity and the end effect will be significant. This violates the truncation principle.

Mathematics of Frequency Independence

The derivation of frequency independence given in this section follows the work from Rumsey,^{1,2} Elliot,⁷ and DuHamel and Isbell⁸ and is valid for spherical coordinate systems, r , θ , and ϕ . The following assumptions have been made:

- The antenna ports are symmetric around the origin and the distance between the ports is infinitesimally small.
- $\theta = 0^\circ$ is the axis of symmetry.
- The antenna is infinite.
- The antenna arms are made of a lossless conductor.
- The medium is homogeneous and isotropic.
- The outline of antenna arms can be described with the parametric formula $r = r(\phi, \theta)$, where r , ϕ , and θ are spherical coordinates and $r(\phi, \theta)$ is the radius vector to any point on the antenna arms.

FIGURE 13-2 Schematic of two-arm geometry. The full structure is that of a planar six-arm self-complementary log-periodic saw-tooth antenna.

To scale the antenna performance to α times lower in frequency, i.e. $f' = f/\alpha$, the electrical dimensions of the original must be maintained. Thus, all defining points on the antenna arms must be multiplied with the same factor. The radius vector now becomes

$$r' = \alpha \cdot r(\phi, \theta) \quad (13-2)$$

Figure 13-3 depicts an example of original and scaled geometry with $\alpha = 2$. The solid circle in the middle denotes the infinite precision of the feeding region. Therefore, the scaling is equivalent to the rotation of the geometry by the angle ϕ' around the fixed antenna terminals. Mathematically,

$$r' = \alpha \cdot r(\phi, \theta) = r(\phi + \phi', \theta) \quad (13-3)$$

Equation 13-3 clearly shows that the two antennas will have the same performance at two frequencies related by α , except for the associated azimuth rotation ϕ' . Additionally, the scaling factor α and associated azimuth rotation ϕ' are mutually dependent and invariant to any other parameter of the antenna. Thus, after taking partial derivatives ($\partial/\partial\phi$ and $\partial/\partial\phi'$) of both sides in Eq. 13-3,

$$\alpha \frac{\partial r(\phi, \theta)}{\partial \phi} = \frac{\partial r(\phi + \phi')}{\partial \phi} = \frac{\partial r(\phi + \phi')}{\partial(\phi + \phi')} \frac{\partial(\phi + \phi')}{\partial \phi} = \frac{\partial r(\phi + \phi')}{\partial(\phi + \phi')} \quad (13-4)$$

$$r(\phi, \theta) \frac{d\alpha}{d\phi'} = \frac{\partial r(\phi + \phi')}{\partial \phi'} = \frac{\partial r(\phi + \phi')}{\partial(\phi + \phi')} \frac{\partial(\phi + \phi')}{\partial \phi'} = \frac{\partial r(\phi + \phi')}{\partial(\phi + \phi')} \quad (13-5)$$

FIGURE 13-3 Notion of scaling through rotation of an infinite FI geometry

Because the right-hand sides of Eq. 13-4 and Eq. 13-5 are the same,

$$\frac{1}{r(\phi, \theta)} \partial r(\phi, \theta) = \left(\frac{1}{\alpha} \frac{d\alpha}{d\phi} \right) \partial \phi = a \partial \phi \quad (13-6)$$

where $a = \alpha^{-1} d\alpha/d\phi$ is a constant. The solution to Eq. 13-6 is

$$r = r(\phi, \theta) = f(\theta) \exp(a\phi) \quad (13-7)$$

where $f(\theta)$ is the arbitrary functional dependence of antenna structure on angle θ . An antenna described by Eq. 13-7 is frequency independent. For the example shown in Figure 13-3, the infinitely large structures represented by solid and dotted lines follow the same growth rate a and the dependence with elevation angle $f(\theta) = \text{constant}$. When the scaling factor is $\alpha = 2$, the original equiangular spiral (solid line) *rotates* in azimuth by $\phi' = \log 2/a$ to conform to the dotted spiral structure. Thus, the antenna scaling is equivalent to a rotation, and the performance at any two frequencies f_1 and αf_1 must be the same except for the rotation ϕ' in azimuth. The rotation of the antenna pattern with frequency is experimentally verified with the equiangular (log-) and other spiral antennas.

By closely examining Eq. 13-7, the following special cases can be derived:

- *Planar equiangular spiral* $f'(\theta) = A\delta(\pi/2 - \theta)$, where A is constant and $\delta(\pi/2 - \theta)$ is the Dirac delta function clearly defining a planar structure.
- *Conical equiangular spiral* $f'(\theta) = A\delta(\beta - \theta)$, where β is the apex angle of the cone while the spiral arms are projected onto the cone surface.
- *Conical screw* The equiangular spiral is projected onto the volume (not surface) between the two concentric cones having different apex angles.
- *Log-periodic planar sheet* Taking $\phi = \text{constant}$ cut through a conical screw with axis on the θ axis. A drawing of the self-complementary log-periodic antenna⁸ is shown in Figure 13-4. Rotation of this planar structure around the arm's symmetry axis will give a

FIGURE 13-4 Drawing of the first planar two-arm sheet log-periodic antenna (after R. H. DuHamel and D. E. Isbell⁸ © IEEE 1957)

FIGURE 13-5 A four-arm self-complementary sinuous antenna (a) and its \log transformation (b)

biconical screw. Log-periodic structures can be obtained by utilizing the transformation $z = \ln(w)$, where $z(x,y)$ and $w(\rho,\phi)$ represent two spaces. This transformation is depicted in Figure 13-5 for a four-arm self-complementary sinuous antenna.

13.2 SPIRAL ANTENNAS

L to Ku band radar developments after the Second World War created a need for compact, flush-mounted antennas and their use for electronic countermeasures (ECM) on aircraft platforms. Broadband, wide beamwidth, circularly polarized sensing capabilities were thus highly sought after. Interestingly, the discovery of an antenna capable of satisfying all those requirements came unexpectedly. In 1954, although discouraged by many experts, E. M. Turner wound a long-wire dipole into a spiral form and connected its terminals to a two-wire feedline.⁹ At that time, the largest antenna bandwidths were on the order of one octave, but the results obtained with the first spiral experiment were so encouraging that an immediate research effort was launched. At the present time, spirals and other frequency independent antennas are irreplaceable components of many communication platforms, various electronic warfare, ECM, and direction-finding systems, and atmosphere, ground, and space exploration stations, and so on.

Spiral antennas are inherently circularly polarized radiators with relatively constant input impedance and radiation patterns over wide frequency ranges. Bandwidth is determined by the fine precision of the feeding region (high frequencies) and overall spiral aperture size (low frequencies). Often the balun feed limits antenna performance, though very wideband feeds have been devised. Spirals can be designed in various planar or conical shapes, with the most common configurations being the equiangular^{2,10,11} and Archimedean spirals.¹² The finite features of spiral aperture prohibit its frequency independent operation for wavelengths greater than the antenna aperture circumference and less than the diameter of its feeding region. Spiral antennas operate in a so-called 3W way—as a fast Wave, leaky Wave, and traveling Wave antenna. Basically, the *traveling* wave form of the excited currents on the spiral arms allows for its broadband performance. This wave is *fast* due to the mutual coupling between neighboring arms and *leaks* energy while propagating on the line to produce radiation.

Spirals can be designed with different numbers of arms, but typically two or four arms are used. The number of arms and their excitation phase/amplitude difference determines antenna performance, which is frequently described using spiral modes. Until recently, it was generally accepted that the number of broadband spiral modes that can be excited using an N -arm spiral is $N-1$ (see pages 108–109 of Corzine's and Mosko's *Four-Arm Spirals*¹³). However, in the article by Filipovic, Stutzke, Buck, Mu, and Kefauver, the broadband dual-mode operation of a two-arm slot spiral was successfully demonstrated.¹⁴ Two-arm spirals are most frequently used to operate in the 1st (mode 1, $m1$, sum, or Σ) mode, which is obtained when the arms are excited 180° out of phase. Radiation leakage occurs throughout the propagation path of the current traveling wave, with the most efficient radiation from the ring one wavelength in circumference. When operating in this mode, the spiral directs its radiation toward broadside.

Spiral antennas can be classified (with respect to the type of transmission line supporting the excited traveling wave) in two major groups: printed or wire spirals and slot spirals. Although the first published records of spiral research were on slot spirals,^{9–11} the majority of publications and patenting have occurred for printed geometries.^{4,5,12,13} The main reason is that multiarm designs are more easily realized with printed spirals. Additionally, once multi-octave broadband matching techniques were developed, vertical feeds were realized and many aperture designs became feasible. Other spiral designs have also been introduced, including the spiral mode microstrip (SMM) antennas, realized from microstrip lines wound into a spiral shape.¹⁵

Basic Principles

The *radiating ring theory*, also known as *band theory*,¹² is used to describe the theoretical principles behind the operation of spiral antennas. The band theory will be demonstrated on the simplest and most commonly used spiral antenna: a two-arm, planar, wire spiral antenna operating in mode 1. As depicted in Figure 13-6a, the spiral is fed from its center at ports A and A' , ideally with equal amplitudes and a 180° phase difference. When fed with an ideal balanced line, and assuming a discontinuity free aperture, the spiral will support propagation of the forward traveling wave. Mode 1 radiation will predominantly occur from a ring with approximately one guided wavelength (λ) circumference. When excited to operate in this mode, spiral currents at points B and B' , which belong to neighboring arms, will be directed the same way, i.e. they will have the same phase value. The same is true for diametrically opposite points C and C' . The nonradiated traveling wave currents will flow past this region, and if the size of the spiral permits, radiate in the next properly phased section. This will occur at a circumference equal to three guided wavelengths (mode 3 for a two-arm spiral). If the spiral is not large enough, the currents will reach the end of the spiral arms where they are either absorbed or reflected back toward the spiral's center. Note that if the size of the spiral is large enough, the in-phase current conditions will show up at odd guided wavelength circumferences of the spiral and higher order modes will radiate. This condition is known as *overmoding*. If attenuation of the forward traveling wave through radiation and dissipation in the lossy termination are insufficient, the currents will reflect back from the end of the spiral and backward traveling waves will be generated. The corresponding radiation of this current wave will be cross-polarized. The majority of backward current wave power will also leak in the odd wavelength circumference regions. Any remaining power will arrive at the spiral input ports (if perfectly matched) and show up as increased input VSWR. The phase of the traveling wave current is shown in Figure 13-6b, where two different shadings denote the instantaneous phases between $0-180^\circ$ and $180-0^\circ$. The mode regions with currents directed the same way are clearly seen.

FIGURE 13-6 Band theory for mode 1 excitation (a) and current phasing (b)

A similar radiation process occurs with other modes and different numbers of arms. For example, a four-arm CCW spiral fed antenna in mode 1 (total phase progression of 360° at the input ports, i.e. the feed phase vector is $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$) will radiate higher modes of orders 5, 9, $4m + 1$, $m = 1, 2, \dots$ if the spiral is large enough to support those modes. When fed with 720° phase progression between input ports (feed-phase vector is $\{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$), the spiral will operate in mode 2 (m_2 , difference or Δ), and overmoding will show up at radiating rings at 6, 10, $\dots 4m + 2$, $m = 1, 2, \dots$ guided wavelength circumferences. Mode 1 and 2 regions of a four-arm spiral are shown in Figure 13-7. Overmoding sometimes occurs due to imperfections in the feed circuitry, loose or improperly phased cables, material impurities, and other conditions capable of alternating the natural progression of the current traveling wave. This type of overmoding is not a function of the number of arms and is typically evenly distributed across the possible modes providing the errors are random. For the same four-arm spiral example used in Figure 13-7a, the errors of this type will be distributed across all modes (0, 2, 3, etc.).

Different Spiral Forms

The most frequently used spiral shapes are Archimedean and equiangular (log-periodic) spirals in planar or conical form. These shapes in planar form are drawn in Figure 13-8.

FIGURE 13-7 Four-arm spiral currents depicting mode 1 (a) and mode 2 (b) radiation regions

FIGURE 13-8 Four-arm Archimedean (a) and equiangular (b) spirals. Shown also are the equations used to generate the outline of their arms.

The Archimedean spiral has a constant arm width and constant separation between arms through the entire aperture. The defining equation for this antenna is $r = r_0 + a\phi$, where r_0 is the starting radius, a is the growth rate, and ϕ is the progressive growth angle. The equiangular spiral has progressively increased arm width and separation between the arms as they open toward the outside. This shape can be entirely described by angles and is the basis for the frequency independent principles (see Section 13.1). The defining equation for an equiangular spiral is $r = r_0 e^{a\phi}$, where r_0 is the starting radius, a is the growth rate, and ϕ is the progressive growth angle. Another term frequently used to describe tightness of the equiangular spirals is the so-called expansion factor (EXP), defined as $EXP = e^{2\pi a}$. For an expansion factor of 2, the spiral radius, as well as the arm width and separation between the arms, will double for each turn. Shown in Figure 13-8 are also the equations for the angles subtended between the radius vector and the tangent on the spiral line at the same point along the arms. For the Archimedean spiral, this angle will depend on the radius, r , while with the equiangular structure, this angle is constant.

Two-arm Spirals

The minimum number of arms needed for single-mode broadband operation is two. Single arm spirals have been designed for some narrow-band applications and will not be discussed in this chapter.¹⁶ The most frequently used two-arm spirals are two-arm Archimedean spirals. A commercial version of this antenna is shown in Figure 13-9. These 5 cm diameter spirals work from 2 to 18 GHz and are available in both RCP and LCP versions. The depth of the cavity backing is almost as large as the antenna diameter. About half of this depth is due to absorber loading and the remaining is due to the integrated balun. The absorber loading significantly reduces the interaction between the metal backing and the spiral aperture. Use of absorber loading reduces antenna efficiency to a maximum of about 50 percent; however, the pattern uniformity over the operating bandwidth is that of a freestanding structure. Integrated within the cavity is also a vertical balun/impedance transformer connected between the spiral ports (in the center) and the connector on the back. The copolarized and cross-polarized gains of this antenna vary little, and the axial ratio is better than 1 dB throughout the band. The axial ratio is highly dependent on the termination method used, especially toward the low end of the operating band (near one wavelength circumference for a mode 1 spiral).

FIGURE 13-9 Two 5-cm diameter complementary Archimedean spirals terminated with absorptive paint and a 100- Ω resistor; arm width $W \approx 0.58$ mm (Courtesy Loral Randtron Systems)

The typical impedance and far-field performances of a well-designed 5-cm diameter two-arm freestanding spiral without end termination are shown in Figure 13-10. The low-frequency ripples in impedance and high axial ratio denote the effects of the backward wave and are the consequence of unterminated arm ends. At the low-frequency end, the diameter of the antenna is not large enough to support the radiation of the $m1$ through the entire active region, thus a strong backward wave exists on the arms. When this wave

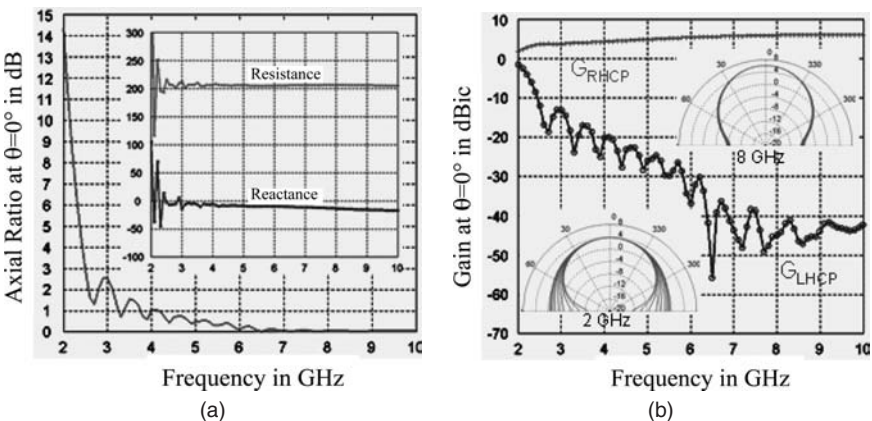

FIGURE 13-10 Broadside axial ratio and input impedance (a), and co/cross-polarized broadside gains with overlaid 36 azimuthal cuts at 2 and 8 GHz (b) of a free-standing self-complementary two-arm spiral. These results are obtained with the method of moments code FEKO.

couples to the feed, it deteriorates the antenna impedance. The radiated power of the backward wave is high, so that the two circularly polarized patterns are superimposed, giving rise to the linearly polarized performance. Additionally, the omnidirectionality deteriorates at 2 GHz as seen from the spread of 36 overlaid copolar patterns shown in the inset of Figure 13-10*b*. At 8 GHz, this spread is significantly smaller, and a symmetric radiation pattern is obtained.

Several variations of two-arm spirals are shown in Figure 13-11. Different metal to nonmetal (slot) ratios are typically used for tuning the impedance at the antenna ports. However, the most uniform far-field performance is obtained with self-complementary spirals. The differences in performance between the tightly wound Archimedean and equiangular spiral are not significant, and sometimes a combined growth is utilized. Actually, the far-field of tightly wound Archimedean and equiangular planar spirals is undistinguishable. However, for conical projections, the differences in beamwidths can be measured.¹⁷

Multiair Spirals

The interest in spirals with more than two arms was ignited by Paul Shelton in 1960. He proposed three- and four-arm spiral designs for multimode operation (see Appendix A in *Four-Arm Spirals* for the copy of the original letter¹³). Shelton recognized that for proper phase progression at the input ports an extra arm (reference) was needed; thus to achieve two broadband modes, at least three arms were required. His finding discontinued the ongoing research regarding demonstration of two broadband modes from two-arm spirals.¹⁸ Since then, it has been generally accepted that an N -arm spiral can radiate only $N - 1$ broadband modes. Therefore, the minimum number of arms for a multimode spiral is three. A unique feature of the three-arm spiral is that the first and second modes have the same impedance. However, four arms are generally used due to the more complex feed network, often called *beamformer* or *modeformer*, needed for the three-arm spiral (feed phase vectors are $m_1 \{0, 120, 240^\circ\}$ and $m_2 \{0, 240, 480^\circ\}$). For dual-polarized spirals, such as the *Modulated Arm Width (MAW)* spiral,¹⁹ a minimum of five arms are required for multimode operation. Due to beamformer simplicity, six or eight arms are generally used. Shown in Figure 13-12 are wire models of two-, four- and six- arm log-spirals with the same exponential factor $\text{EXP} = 1.5$. Starting radius is 1.25 mm; ending radius is 3 cm.

When comparing the far-field performance of these antennas, the major differences are in the symmetry of the azimuthal patterns (WoW, which will be discussed more in the next section) and in the broadside axial ratio (cross-polarization). The copolarized patterns are virtually indistinguishable. The complexity of the mode-forming network and arm terminations are the main reasons for the lesser use of spirals with more than two arms.

FIGURE 13-11 Drawing of a self-complementary Archimedean (a), non-self-complementary Archimedean spiral (b), and self-complementary equiangular (c) two-arm spirals

FIGURE 13-12 Two- (a), four- (b), and six-arm (c) equiangular spirals with EXP = 1.5

Shown in Figure 13-13 are the cross-polarization levels and the 3-dB beamwidth for two-, four-, and six-arm spiral antennas when designed for mode 1 operation. Spirals are free-standing, and unterminated arms are made of a perfect electric conductor. The increased number of arms contributes to the improved cross-polarization levels, primarily due to the increased coupling in the active region, and better filtering of negative (cross-pol) modes. The copolarized patterns are unaffected by the number of arms used.

Spiral Modes

Spiral modes were first theoretically studied in the early 1960s^{20,21} when radiation conditions for orthogonal radiation modes of infinite arm spirals were derived. It was shown that an arbitrary feeding arrangement at the spiral arms can be decomposed into the sum of several modes, giving rise to the characteristic far-field radiation. Multimode spirals have been traditionally used for monopulse direction finding,¹³ where amplitude and phase comparisons between the multiple modes can provide information on azimuth and elevation of the incoming signal.

The notion of spiral modes is associated with the desired or undesired radiation conditions from a spiral aperture. Desired radiation is that of the dominant modes for which the spiral is designed. Undesired radiation is that occurring from various imperfections (beamformer errors, phase matching from the cables or balun, and so on) or excitation

FIGURE 13-13 Cross-polarization difference (a) and 3 dB beamwidth (b) of two-, four-, and six-arm spirals

FIGURE 13-14 Effect of feed imperfections on the mode 2 radiation pattern of a four-arm spiral

and radiation from the higher order modes. For example, for a four-arm spiral designed to operate in mode 2, the imperfections can cause radiation from modes 1, 3, 4, etc., while the higher-order mode is mode 6. An example of an undesired mode 4 effect on the mode 2 pattern of a four-arm spiral is shown in Figure 13-14. The pattern undulation with two half sinusoids occurred due to the imperfections in the feeds.

Dominant modes are those for which the proper phase progressions at the feed are devised; for mode m , an overall phase progression of $m \times 360^\circ$ is needed. They are circularly polarized waves radiated from the $m\lambda$ circumference rings and have a far-field phase progression with m cycles of 360° on any constant θ angle. Only mode 1, both right circular polarization (RCP) and left circular polarization (LCP), has any boresight component. All other modes have an on-axis null. Higher-order modes are typically unwanted, and they are formed due to the existence of the nonradiated currents on the spiral aperture outside the nominal radiating ring. They can be suppressed by reducing the size of the spiral so its circumference is smaller than $m\lambda$, where m is the unwanted mode. Improving the efficiency of the radiation through the dominant radiating ring can reduce the negative effects of these modes, and this is recommended for spiral designers. Radiated power of the higher-order modes is to blame for scalloping spiral patterns and significantly increased amplitude wobble on conical spiral pattern cuts (the parameter often termed as $WoW^{5,13}$). Shown in Figure 13-15 are the decomposed patterns of desired mode 1 and higher-order modes 3 and 5 of a two-arm spiral on a constant conical cut. The undulations associated with the higher-order modes clearly verify the previous discussion, and special care must be exercised when truly frequency independent performance is needed of a spiral.

FIGURE 13-15 Azimuthal patterns for mode 1 and higher-order modes 3 and 5 superimposed with mode 1

FIGURE 13-16 Radiation patterns of modes $m1$ through $m7$ for an eight-arm freestanding spiral

Computed copolarized radiation patterns for seven broadband modes of an eight-arm equiangular spiral are shown in Figure 13-16. Each higher-order spiral mode peaks successively farther from boresight with only mode 1 having maximum gain at boresight. Approximate beam peak angles and directivities are shown in Table 13-1. These values are typical but there will be minor variations based on spiral design and frequency.

To demonstrate overmoding on a two-arm spiral antenna, the max gains of the operating mode $m1$ and a first higher-order mode, $m3$, are computed for several equiangular spirals with various growth rates and their difference is plotted in Figure 13-17. The tighter growth rates can be utilized to design antennas with high cross-mode difference gains and thus improved patterns. The maximum value shown for $m3$ radiation is -18 dB below the $m1$ gain at 18 GHz.

The WoW at 30° for the antennas given in Figure 13-12 is shown in Figure 13-18. Spirals with a larger number of arms produce more symmetric (pure) radiation patterns due to the progressively higher order of the first contaminating mode. As discussed earlier, for the two-arm spiral, the first higher-order mode is $m3$, while for the four- and six-arm spirals, these are modes $m5$ and $m7$, respectively. Unfortunately, the complexity of the beamformer and the arm terminations prevent the widespread use of spirals with more than two arms.

Dielectric Loading Effects

A spiral is a fast wave antenna and the use of a high dielectric constant and/or thick dielectric can significantly alter its characteristics. Input resistance is reduced and the gain, axial ratio, and pattern purity in general are all degraded when compared with a freestanding spiral. Dielectric loading slows the traveling wave thus reducing the aperture of the active mode. Additionally, the coupling between the neighboring arms is reduced and the radiation through the active region is decreased. This means that the forward traveling wave, after passing the desired region, will have more energy and radiate in the higher order modes, contributing to the excessive far-field contamination. For some applications, pattern purity is

TABLE 13-1 Directivity and Beam Peak Elevation Angles for Seven Modes of an Eight-arm Freestanding Spiral

Spiral mode	$m1$	$m2$	$m3$	$m4$	$m5$	$m6$	$m7$
Beam peak in $^\circ$	0	36	48	52	54	56	57
Max directivity in dBic	8.5	6.3	6.3	6.5	6.7	6.8	6.8

FIGURE 13-17 Mode 3 content (relative to mode 1) of a 6-cm diameter two-arm equiangular spiral with various growth rates shown in inset

not essential so that the associated miniaturization due to the loading is usually computed as a relative reduction of the lowest frequency for which the spiral has a prescribed gain value at the beam peak.²² Pure modal patterns can still be obtained, but the number of spiral arms need to be increased or the operational bandwidth is decreased (Eq. 13-15). Interestingly, and owing to the radiation ring theory of operation, this translation of the frequency dependent gain curve is proportional to $(\epsilon_{r,\text{eff}})^{1/4}$, as compared to the $(\epsilon_{r,\text{eff}})^{1/2}$ impedance shift, where $\epsilon_{r,\text{eff}}$ is the effective dielectric constant of the associated stripline model.²³

FIGURE 13-18 WoW at 30° for spirals given in Figure 13-12

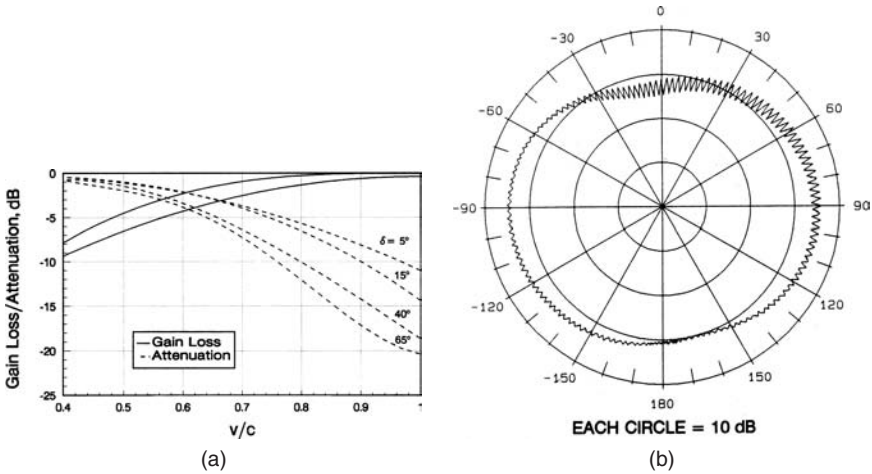

FIGURE 13-19 (a) One λ -ring gain loss and attenuation versus v/c for an equiangular spiral. (b) Measured rotating linear conical-cut pattern of a 5 cm cavity-backed Archimedean spiral with $v/c = 0.65$ (Courtesy of Loral Randtron Systems)

Effects of dielectric loading are best shown in Figure 13-19. The free-space case has the lowest gain reduction and highest attenuation of the traveling wave through the radiating region. The more pronounced the loading (lower wave velocity v), the more bound the traveling wave is to the spiral and the less it radiates. The conical-cut pattern of a spiral with $v/c = 0.65$ taken at the $\theta = 60^\circ$ clearly depicts the undesired loading effects on the pattern purity. The WoW of about 8 dB, the variation of the axial ratio from 0.1 to 4 dB, and two undulations offer clear proof of a very high-level of energy being radiated from the $m3$ ring, i.e. reduced attenuation through the $m1$ active ring.

Far-Field Modal Decomposition

To investigate the composition of the modes in a radiation pattern of a spiral antenna, a technique referred to as *pattern modal decomposition* is often used.^{5,13,24} The radiating modes of an N -arm spiral can be obtained by producing a phase progression between adjacent arms at the feed points equal to $2\pi m/N$, where $m = 1, 2, \dots$ is the desired mode of operation. To compute the modal content of the radiated field, the phase progression is applied to the arms of the spiral through complex voltage coefficients defined by

$$V_{k,m} = V_{0m} \cdot e^{\frac{-j2\pi m(k-1)}{N}} \quad (13-8)$$

where $k = 1, \dots, N$ denotes the arm, V_{0m} is a constant amplitude, and j equals $\sqrt{-1}$. Equation 13-9 has the restriction

$$\sum_{k=1}^N V_{k,m} = 0 \quad (13-9)$$

for each mode. A determination of the modal fields in terms of the measured pattern is then obtained by applying

$$E_m(\theta) \cong \frac{1}{N_\phi} \cdot \sum_{k=1}^{N_\phi} V_{k,m}^* \cdot E(\theta, \phi_k) \quad (13-10)$$

where $E_m(\theta)$ are the coefficients to the discrete Fourier series representation of $E(\theta, \phi_k)$. N_ϕ is the number of points per conic cut (at a constant theta value), in the far-field pattern data, and the highest number of ambiguity free modes that can be resolved is equal to $N_\phi/2-1$. $E(\theta, \phi_k)$ can be measured pattern data or calculated from electromagnetic models.

To demonstrate the capabilities of this technique, the beamformed patterns of an eight-arm RCP spiral are decomposed into modes, as shown in Figure 13-20. Both left- and right-handed modes supported by this structure are measured, and the power in cross-polarized modes (negative ones) is much less than that of the copolarized fields. Also clear from this figure is that the higher-order modes “turn on” at progressively higher frequencies. A single arm measurement without beamformer can also be decomposed into basic spiral modes, thus providing a significant amount of data, i.e., all possible spiral modes from a single port measurement.

Mode Impedances

The input impedance to the ground for a self-complementary N -arm structure in free space is derived by Deschamps²⁵ and is given as

$$Z_m^{\text{fs,comp}} = \frac{\eta_0/4}{\sin\left(\frac{m \cdot \pi}{N}\right)} \quad (13-11)$$

where $\eta_0 = 120\pi \Omega$ is the impedance of the free space. The integer, m , denotes the eigenvalue or characteristic mode ($m = 1, 2, \dots, N-1$) where N is the number of arms on the structure.

FIGURE 13-20 Power in each mode for a single arm of a 25-cm diameter eight-arm spiral

TABLE 13-2 Input Impedance of Free-space Self-Complementary Spirals

# Arms	Spiral Mode						
	1	2	3	4	5	6	7
2	94.2						
3	108.8	108.8					
4	133.3	94.2	133.3				
5	160.3	99.1	99.1	160.3			
6	188.5	108.8	94.2	108.8	188.5		
7	217.2	120.5	96.7	96.7	120.5	217.2	
8	246.3	133.3	102.0	94.2	102.0	133.3	246.3

Modal impedances for self-complementary two- to eight-arm spirals are computed using Eq. 13-11 and the results are shown in Table 13-2. Interestingly, only a three-arm spiral has the same modal impedances for m_1 and m_2 , making it an excellent candidate for monopulse direction finding. However, the complexity of the beamforming network for this antenna reduces its practical application. In practice, these theoretical impedances are lowered due to the finite thickness of the metallic parts on an antenna as well as the inevitable dielectric loading (used for mechanical support).

To impedance match the spiral to a particular mode, the arm to gap ratio (A/G) at the spiral feed points can be adjusted to match to the feed cable impedance (usually 50Ω). Because spirals radiate most efficiently as self-complementary structures, the noncomplementary feed region should be slowly transformed back to the complementary before the first desired radiation region. As with most impedance transformers, this transition should be at least one-quarter guided wavelength long at the lowest frequency of operation. A drawing of a tapered A/G feed region for an eight-arm spiral is shown in Figure 13-21*a*. For this antenna to simultaneously match both m_2 and m_3 to 50Ω coax, the predicted optimum A/G ratio is about 20 (see Figure 13-22). Impedances for various A/G ratios, modes, and dielectric thickness are computed by Huffman and Cencich.²⁶

FIGURE 13-21 (a) Impedance transformer for an eight-arm spiral and (b) matching section for a four-arm spiral antenna²⁸

FIGURE 13-22 Theoretical input impedance versus A/G width ratio for modes 1, 2, and 3 of an eight-arm spiral antenna on a 0.01-inch-thick 2.1 dielectric constant substrate

Simultaneous matching of spiral mode impedances is a challenging problem and several methods have been devised. These methods utilize a feedline structure that is highly decoupled at the beamformer input (all input ports are 50Ω , regardless of mode), and strongly coupled at the spiral interface (impedance is dependent on input excitation). In the feedline section, near the spiral, coupling is obtained similar to that between the arms in a spiral antenna. A six-arm spiral with a coaxial-type coupled feedline²⁷ has maximum return loss of -13 , -17 and -16 dB for the first three modes. Average return loss over the 4:1 bandwidth was -18 , -22 and -24 dB for these same modes. Another approach to simultaneously match both sum and difference modes of a four-arm spiral is shown in Figure 13-21*b*.

Spiral Feeding Techniques

A number of different feeding techniques have been developed for spiral antennas. Some include not only balanced to unbalanced transitions but also impedance transformation. The tapered microstrip balun,²⁹ Marchand balun,³⁰ and 180-degree hybrids with coaxial feeds are commonly used for two-arm printed spirals. The tapered microstrip balun, shown in Figure 13-23*a*, has the advantage that the spiral impedance can be matched by tapering the width of the strips. It can be designed for bandwidths several octaves wide. An infinite (Dyson) balun feed¹⁰ has theoretically unlimited bandwidth and is the most frequently used horizontal feeding technique. The outer conductor of the coaxial cables is soldered to the metallic portion of the spiral (in between the slot arms), and a transition to the slotline is provided in the center. A two-arm slot spiral with this balun is shown in Figure 13-23*b*. The dummy cable is used to provide the geometrical symmetry; however, if not used, the beam squint is not that significant. As shown in Figure 13-23*c*, a vertical single coaxial feed can be easily implemented with a four-arm spiral operating in mode 2.³¹ Finally, the most general feeding arrangement for spirals with more than two arms is shown in Figure 13-23*d*. Here, coaxial feedlines are used, where the outer conductors of these coaxial cables are soldered together to form a compact coaxial cluster. To further reduce unwanted feed line radiation,

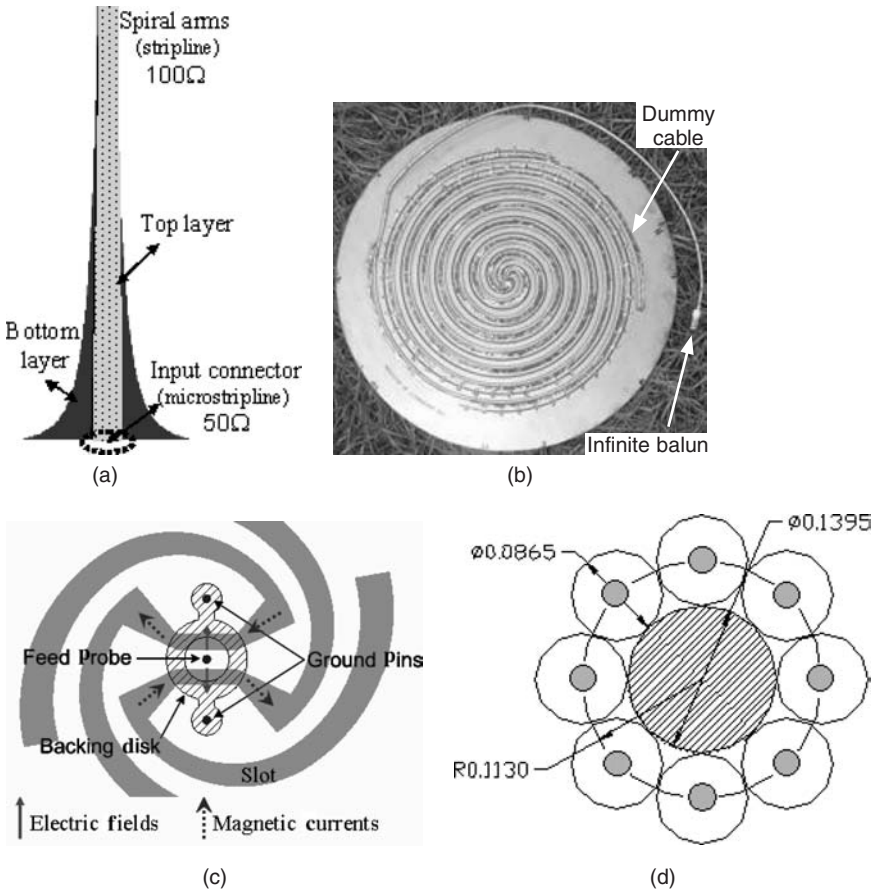

FIGURE 13-23 (a) Parallel strips balun/transformer, (b) infinite coaxial Dyson balun, (c) vertical coaxial balun, and (d) coaxial cluster feed

absorber paint is sometimes used to coat the outer conductor of the coaxial feedline cables between the beamformer and spiral.

If the spiral start radius is too large, excessive energy will leak through the mode 1 radiation region. Spiral size permitting, this energy will radiate in higher-order modes, thus significantly contaminating its far-field. The starting radius guideline for spirals with relatively small growth rates ($EXP < 2$) is

$$R_{\text{start}} = \frac{\lambda_{\text{high}} m_{\text{lowest}}}{6\pi} \quad (13-12)$$

where λ_{high} is the guided wavelength of the highest frequency of operation and m_{lowest} is the mode order of the lowest desired mode of operation. Additionally, the feed region of the spiral can interact with the feeding cables and create currents that propagate on the outside of the cables. This can severely deteriorate the radiation patterns and also provide unwanted interference. Since multiarm spirals are commonly fed with some form of coaxial clusters, special care must be exercised when the minimum spiral radius is determined.

TABLE 13-3 Maximum Mode 1 Frequency for Coaxial Bundle Feed (for commercially available cables)

Arms/Coax	Maximum frequency of operation in GHz			
	0.141"	0.085"	0.047"	0.034"
2	7	12	22	30
4	6	10	18	25
6	5	8	14	20
8	4	6	12	16

The approximate upper frequency limits for quality mode 1 radiated patterns for various coaxial cable sizes are summarized in Table 13-3.

As discussed earlier, a spiral needs to be $m\lambda$ in circumference to support the radiation of mode m . Since the radiation region is actually a finite width ring, it will be severely truncated if the circumference is only $m\lambda$. A good rule to avoid unnecessary truncation of the radiating ring of a tightly wound spiral ($\text{EXP} < 2$) is expressed in

$$D \geq \frac{(m_{\text{highest}} + 0.5)\lambda_{\text{low}}}{\pi} \tag{13-13}$$

where D is the spiral diameter, λ_{low} is the guided wavelength of the lowest frequency of operation, and m_{highest} is the mode order of the highest desired mode of operation. For higher spiral efficiency, the numerator of Eq. 13-13 should be increased to $(m_{\text{highest}} + 1)\lambda_{\text{low}}$. Loss (directivity minus gain) versus spiral circumference for a four-arm printed equiangular spiral over an absorptive cavity is shown in Figure 13-24. At least 3 dB of this loss can be attributed to absorption of the back hemisphere pattern of the spiral.

FIGURE 13-24 Difference between directivity and gain for broadband modes of a four-arm printed spiral backed by an absorptive cavity

Spiral Backing Techniques

A planar spiral antenna radiates bidirectionally, with opposite polarization senses in the two hemispheres. For most applications unidirectional radiation is required. The most commonly utilized approaches for eliminating the backward radiation of a planar spiral are use of either a reflective- or absorber-filled cavity. Absorptive cavities dissipate backward radiation using carbon-filled materials in some form of honeycomb, syntactic foam, or polyurethane foam. Typical configuration of an absorber-backed spiral is shown in Figure 13-25. A graded absorber is used to taper match the air to the heavily loaded carbon material. If the absorber is placed too close to the spiral element, additional attenuation of the forward traveling wave will occur contributing to increased losses (greater than 3 dB). A dielectric lens placed on the top of the spiral can be used to recover some losses (~ 1 dB) due to the redistribution of the radiated power in two hemispheres.

Computed effects of the perfect electric conductor (PEC) or perfect magnetic conductor (PMC) backings on the WoW of a good two-arm spiral antenna are shown in Figure 13-26.³² Neither of the two backing configurations can provide uncontaminated far-fields over a broad frequency range, although they can be utilized over limited bandwidths. Compared to the free-space (or effectively well-designed absorber-backed antenna), the pattern asymmetries are excessive. In the case of PEC backing, the fields reflected off the metallic bottom undergo polarization reversal and constructively add in the far-field (at broadside) if the bottom

FIGURE 13-25 Sketch of an absorber backed cavity along with accompanying parts of a practical spiral

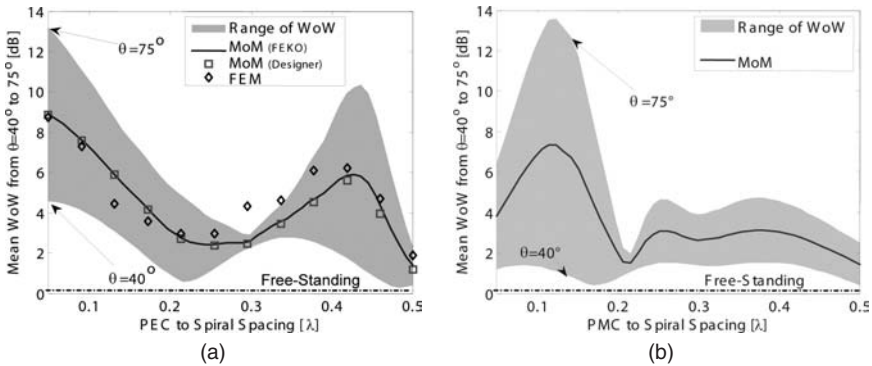

FIGURE 13-26 The effect of infinite PEC (a) and PMC (b) backings (at different depths) can be observed on WoW and azimuthal pattern symmetry. The mean value of WoW from $\theta = 40^\circ$ to 75° is plotted with the range over the same shaded elevation span. The absorber-backed or freestanding value is also included. The WoW of the freestanding structure varies from 0.08 dB at $\theta = 40^\circ$ to 0.3 dB at $\theta = 75^\circ$ (after M. Buck and D. Filipovic³² © IEEE 2006).

is a quarter wavelength from the spiral. Overmoding will occur if the spiral size permits creation of higher-order mode active regions. Thus, an effective way for suppressing overmoding effects is to increase the number of spiral arms such that the active region of the lowest-order parasitic mode falls outside of the spiral aperture. For example, if you want to design a mode 1 spiral to operate in 2–20GHz range with a 5 cm aperture diameter and absorber-free metallic backing, how many arms should you consider? Assuming ideal conditions on the spiral (zero width of the active region, no miniaturization, and ideal arms termination) and knowing that the circumference of the active region for the first parasitic mode is $(N + 1)\lambda_{\text{high}}$, you can compute the number of arms as $N \geq \pi/\lambda_{\text{high}} - 1$, i.e., at least $N = 10$ arms are needed. A more appropriate inequality for computing the number of arms for this type of spiral antenna is

$$N = \left\lfloor \frac{f_{\text{high}}}{f_{\text{low}}} (m + \Delta) \right\rfloor - m + 1 \quad (13-14)$$

where f_{high} and f_{low} are highest and lowest frequency of operation, m is the desired mode of operation ($m = 1$ in the given example), $\lfloor x \rfloor$ is the integer part of x , and Δ is the safety factor depending on the width of the active region, depth of metallic backing, and established criteria for tolerable cross-modal difference (typical values for Δ are ~0.5 to 1). Note that multiarm designs have higher complexity and price associated primarily with the beamformer. Often the increase in antenna efficiency does not compensate for the excessive cost (remember that the beamformer must have the same bandwidth as the antenna; thus for a 12-arm spiral maintaining 30° phase progression between neighboring ports, over a decade of bandwidth is a very difficult task).

Effects of the metal backing are also shown in Figure 13-27, where modal content of metal backed and free-standing two-arm spirals are compared. The power radiated by the higher-order modes of the free-standing spiral is significantly lower. Note that the cross-modal difference of 10 dB typically causes WoW on the order of 6 dB on wide-angle conical cuts. A metallic backing spaced farther than $\lambda/4$ will begin to degrade the boresight gain. At a height of $\lambda/2$, the mode 1 pattern will have a null on boresight but still maintain mode 1 phase characteristics.

FIGURE 13-27 Modal contamination of cavity-backed and free-standing two-arm spiral

Arm Termination Techniques

When attenuation through the active region(s) is insufficient, the residual traveling wave will reach the arm ends, encounter a discontinuity (open end for printed and short end for slot spirals), and reflect back toward the feed. Simultaneous existence of two oppositely directed traveling waves on the spiral create conditions for a standing wave, thus increased VSWR and crosspol. To mitigate these effects, special care must be taken in the design of arm terminations. Various techniques for terminating the spiral arms have been devised in the past including

- Distributed resistive loading in the form of matched tapers such as exponential or Klopfenstein tapers (preferred method for slot spirals) (see Figure 13-23*b*, and for a detailed design, see Nurnberger's and Volakis's paper³³)
- Absorber paint on the last turn (or on a few turns, see Figure 13-28*a* with ambidextrous spiral configuration)
- Resistive termination to the spiral cavity, as shown in Figure 13-28*b*
- Single resistor loaded microstrip or stripline transition or a high-impedance slot circle
- Absorber ring around the spiral perimeter, either on the top (contact) or inside the cavity
- Helix-loaded spiral (absorber loads the helix at low frequencies, see Figure 13-32)
- A thin (thus lossy) multiple turn wire at the spiral perimeter, sometimes painted with lossy material
- Multiple turns of a long, thin arm's extension (see Figure 13-28*c*)

The rule of thumb is that the termination section composed of distributed elements should be at least a quarter guided wavelength long at the lowest frequency of the spiral.

FIGURE 13-28 Photos of several spiral terminations: (a) absorber paint, (b) resistor, and (c) thin arm (Courtesy of BAE Systems)

Conical Spirals

To reduce the backward radiation of a free-standing planar spiral, Dyson wrapped the spiral onto a cone.¹¹ Parameters needed for constructing a conical spiral and a picture of this type of antenna is shown in Figure 13-29. This form can increase radiation toward the cone apex and reduce back hemisphere radiation. Printed and slot designs, including spirals with outer coaxial conductors playing the role of arms, have been realized, and they were fed with some form of Dyson balun. Dyson determined that when the spiral currents are reduce by 3 dB on the high-frequency end (at the top of the cone) and 15 dB (at the bottom of the cone) that the

FIGURE 13-29 (a) Sketch of a conical spiral (after J. D. Dyson¹¹ © IEEE 1965) and (b) two four-arm spirals (Courtesy of GTE-Sylvania Systems Group)

FIGURE 13-30 Conical spiral average front-to-back ratio versus cone angle for various growth rates

radiation characteristics do not greatly change. This finding was important for truncation of the spiral, thus simplifying fabrication while reducing the feed-coax length and the height of the cone. Computed front to back (F/B) ratios for various cone apex angles of a four-arm conical spiral are shown in Figure 13-30. As the cone angle is decreased (the spiral gets taller), the backlobe is reduced, and the directivity increases. Directivity also increases when the spiral is wrapped tighter since more turns cross the active region and coupling between arms is enhanced.

Conical spirals designed to operate in the mode 2 have been utilized for surveillance applications. It was shown that the cone apex angle and other parameters of the spiral can be adjusted to peak the beam at desired angles (see Figure 13-31). These four-arm spirals can be excited with a single 180° hybrid or other two-arm spiral feeding methods. Since at the feed opposite arms have the same excitation, they can be shorted together (without shorting to adjacent arms), leaving only 0° and 180° phasing requirements, the same as a two-arm spiral.

Spiral Miniaturization

A spiral is a fast leaky wave antenna that performs at its best when the traveling wave phase velocity is as high as possible (as an example, see Figure 13-19). Thus, slowing the wave on the spiral arms, though possible, must be exercised with extreme care. Techniques for slowing the wave on the spiral arms include loading the spiral with higher contrast/thickness dielectric material, increasing the length of the spiral arms using modulations or a modified spiral shape, and capacitive and inductive loading of the line. Though some techniques result in acceptable patterns and improved matching conditions, the antenna efficiency typically is reduced (for dielectric loading) and some pattern contamination may occur. A good example of extended low-frequency performance is given in *Four-Arm Spirals*,¹³ where a

FIGURE 13-31 HPBW and beam-peak elevation angle for a 2nd mode four-arm conical spiral⁴

25-cm helix-loaded spiral demonstrated good patterns down to 250 MHz. A similar commercially available realization is shown in Figure 13-32a. As demonstrated by Filipovic and Volakis,³⁴ a 15-cm diameter two-arm meanderline slot spiral, shown in Figure 13-32b, showed good performance down to 250 MHz. The three-dimensional undulations and resulting inductive loading with the variable thickness dielectric (see Figure 13-33) are used by Chen and Volakis²² and impressive low-frequency gain values are demonstrated.

FIGURE 13-32 (a) Helix-loaded spiral (Courtesy of EDO) and (b) in-plane meandered slot spiral

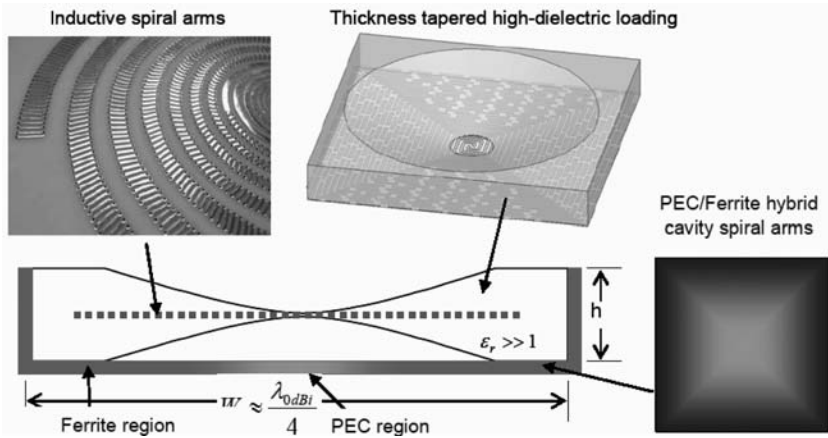

FIGURE 13-33 Spiral miniaturization by combining inductive and dielectric loadings (after C-C Chen and J. L. Volakis²² © Wiley InterScience 2007)

Beamforming

Beamformers, also known as *modeformers*, are used to provide proper phasing of the spiral arms to achieve the desired mode excitations. Phase excitations for the first two modes of four-arm RCP and LCP spirals are shown in Figure 13-34. For a counterclockwise (CCW)-wound RCP spiral, phase excitation of successive spiral arms is given by $p = \frac{-360m(n-1)}{N}$ (in degrees), where $m = 1, 2$ is the mode number, $n = 1, 2, 3, 4$ is the arm number, and $N = 4$ is the number of arms. Note that the theoretical phase distributions are identical for modes 2 RCP and LCP and that the spiral's wrap direction determines the polarization sense. The beamforming networks are typically stripline circuits built as a combination of 90° and 180° hybrids and phase shifters. An excellent treatment of spiral beamformers can be found in *Four-Arm Spirals*.¹³

The modal decomposition of the mode 1 input of a 4×4 Butler matrix beamformer is depicted in Figure 13-35. Complex S_{N1} data are measured from the mode 1 input to each of the four outputs of the beamformer ($N = 1, 2, 3, 4$). This data is then decomposed into the four spiral modes. Both amplitude and phase imbalances contribute to the modal contamination. The top curve is the insertion loss for mode 1, while the remaining curves (modal isolation > 25 dB) represent the contamination level of each of undesired modes, m_2 , m_3 , and m_4 .

FIGURE 13-34 Four-arm phase excitations: (a) mode 1 RCP, (b) mode 2 RCP, (c) mode 1 LCP, and (d) mode 2 LCP

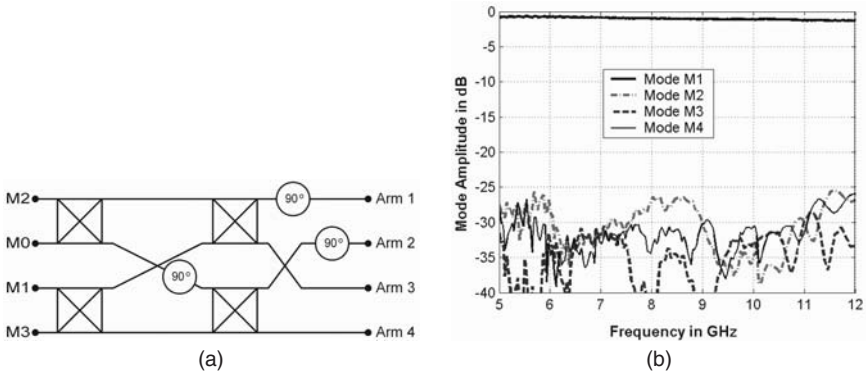

FIGURE 13-35 (a) Four-by-four Butler matrix beamformer and (b) modal decomposition for the spiral modes of a beamformer designed for 5–12 GHz operation

An ideal spiral integrated with this beamformer will have these modal pattern errors, assuming the spiral is large enough to support all the modes. Modal purity of other ports (m_2 , m_3 , and m_4) is determined in the same manner. Mode 4 will not radiate well from a four-arm spiral, but the beamformer modal contamination should be low so it will not excite direct radiation from the spiral feed structure. In general, for an N -arm spiral, mode N has the same input phasing as mode 0, and neither mode typically radiates efficiently. Mode 0 has no radiation region on the spiral, and the mode N impedance is extremely high as the equal phase currents in the feed region have difficulty propagating.

Reflector Feeds

Since spirals have approximately constant beamwidths they make ideal reflector feeds if broadband circular polarization is required. For planar absorptive cavity spirals, a reflector F/D of approximately 0.35 is optimal for mode 1. The spiral phase center is relatively stable across wide frequency ranges and is slightly in front of the spiral element, outside of the cavity, for this configuration. Figure 13-36 shows amplitude taper loss (ATL) and spillover

FIGURE 13-36 Aperture losses for a center-fed reflector with a four-arm planar spiral feed

loss (SPL) versus F/D , for both modes 1 and 2, using measured patterns of a four-arm spiral feeding a center-fed reflector. Maximum mode 1 aperture efficiency is when the F/D is 0.38. Mode 2 is most efficient at a 0.31 F/D . Simultaneous illumination is best at $F/D = 0.36$. Note the ATL + SPL curves are relatively flat and the optimal F/D may be chosen based on other factors such as maximum mode 1 gain or lower sidelobes. With a reflective cavity, the spiral directivity increases and the optimum F/D ratios increase to 0.45 for m_1 , 0.38 for m_2 , and 0.45 for simultaneous illumination of both modes.

Conical spirals have also been used as reflector feeds. The major advantage of conical spirals is improved efficiency due to backlobe reduction. A disadvantage is that the phase center moves with frequency resulting in a quadratic phase loss with frequency for a symmetric reflector. For this reason, the conical spiral feed can have optimal performance at only one frequency. Also, phase centers are not collocated for multiple modes at the same frequency. When used in an offset reflector, a conical feed will have beam-squint versus frequency due to phase center movement. Even with these limitations, conical spirals can be efficient feeds over broad bandwidths. Shown in Table 13-4 are illumination losses of less than 1.5 dB for 10:1 bandwidths using cone angles ($2\theta_0$) of 20 to 40 degrees. More extensive coverage is provided in Milligan's *Modern Antenna Design*.⁵

Lens Effects

Spirals are often realized with contact lenses^{5,13} made as a constant dielectric (hemi) spherical, Luneburg axicon, or as specially designed surfaces for custom-made dielectrics. Contact lenses can improve spiral efficiency by reducing the mismatch between the spiral aperture and free-space. The lower plane wave impedance in the lens medium allows for the spiral/lens configuration to radiate more energy into the upper hemisphere and less energy into the cavity. Care must be taken to ensure the lens substrate material near the spiral has very low loss. Since the spiral transmission region is generally very long (several wavelengths), and the spiral is loaded by this dielectric, losses quickly add up if the lens loss tangent is high. Hemispherical contact lenses will not dramatically change the beamwidth of a planar spiral. Other lens configurations can be made to focus the beam and substantially increase directivity and gain. Multiple spiral modes can be effectively focused using these lenses, and the angle-of-arrival (AOA) capabilities are retained (see Figure 13-37). Wide-angle lenses have been constructed for azimuth symmetric beams that steer out to 60° and beyond. Multimode spirals can be used as feeds and azimuth AOA can be obtained (elevation AOA is usually severely degraded for these types of lenses). Noncontact lenses can also be used, but the spiral efficiency will not be improved. Conical spirals are usually not used due to the short focal length of the lenses and the phase center movement of the conical antenna versus frequency.

Other Spiral Geometries

Spiral antennas have been fabricated in a wide range of geometries not only for improved performance, but also for the reasons of packaging, arraying, and conformal and flush-mounting. For example, square spirals (see Figure 13-38) allow closer packaging in an array environment, and because of longer circumference than round spirals, provide some inherent miniaturization factor ($MF = 4/\pi$) for improved low-frequency operation. Wiggly spirals have modulations in the form of a zig-zag, sinusoid, or meander-line added to the spiral arms to increase arm length and also enhance low-frequency performance. These methods can improve low-frequency performance, but overmoding is still present at higher frequencies. Spirals have also been made on parabolic reflector surfaces and conformal to spherical bodies.

FIGURE 13-38 Circular, square, and hybrid spiral lay-outs

Spiral Modeling

The complexity of spiral geometry and absence of appropriate computational tools (including methods for numerical electromagnetics) in the 1950s limited the study of spiral antennas to primarily experimental efforts. The first theoretical analysis of a spiral antenna was published in 1960,³⁵ where the spiral geometry was approximated by semicircles, and the vector potentials were computed by employing the appropriate Green's function. Although this was a simplified model, the physical understanding of the spiral's operation, including the low- and high-frequency limits, were obtained from this analysis. The availability of faster computers and the introduction of rigorous analysis methods for solving integral equations (numerical methods) was critical for comprehensive theoretical investigation of spiral antennas. Nevertheless, while integral equation methods have been traditionally used for free-standing printed and wire spirals, and for noncavity-backed slot spirals, partial differential equation and volume modeling methods are more appropriate for the cavity-backed spirals and spirals on a finite substrate. The finite element-boundary integral method (FE-BI), developed specially for the cavity-backed Archimedean slot spirals,³⁶ has produced very accurate results.^{23,34} This method combines triangular and quadrilateral prismatic finite elements to obtain the best representation of the electric fields inside an extremely narrow slotline.

Recently, a finite volume-time domain technique (FVTD)³⁷ was used to accurately model realistic spiral geometry, as shown in Figure 13-39. Complex, honeycomb absorber loading, balun, thin dielectric, and fine details of a tightly wound Archimedean spiral are modeled for the first time in its entirety and excellent agreement with measurements has been obtained (see Figure 13-40). Finally, the analysis of spiral antennas has also been performed using commercially available numerical tools including method of moments codes, NEC, FEKO, Ansoft Designer, IE3D, as well as finite element software tools such as Ansoft HFSS and finite difference time domain XFDTD. A comparison between the HFSS, FEKO, and measurements, shown in Figure 13-41, clearly demonstrates the accuracy of these tools in modeling spiral and other FI antennas.

13.3 LOG-PERIODIC ANTENNAS

Log-periodic antennas were introduced in the late 1950s by DuHammel and Isbell.⁸ They derived the analytical formulation of log-periodic principles, including the mathematical description of the geometry, and experimentally verified the proposed principles on a planar sheet (slot) antenna, as shown in Figure 13-4. Continuing this original work and the unpublished work of Isbell, DuHammel and Ore³⁹ noticed that the currents were concentrating on the edges of a planar self-complementary metallic sheet, so they removed the metal from the center and wire-like log-periodic antennas were born. They also demonstrated circularly polarized designs and unidirectional performance with a folded geometry. Design guidelines and the dipole log-periodic antenna with transposed feed, one of the most frequently used radiators, were established by Carrel.⁴⁰ A significant number of contributions have been reported since these early days,^{3,4,5} however, we will only mention the important discovery of a frequency independent log-periodic sinuous antenna by DuHammel.⁴¹ At the time, this was the first single-feed, planar antenna element that was simultaneously multi-octave wideband and omnipolarized.⁴²

Basic Principles

A *log-periodic antenna* is defined as a structure whose electrical properties vary periodically with the logarithm of frequency. If an antenna is realized such that within each period its performance changes within bandwidth-defined conditions (for example, the real part of the input impedance = $70 \pm 20\Omega$, or the gain = 5 ± 1 dBi, etc.), then multi-decade operation can be obtained. To produce the described performance, similar mathematical relationships must be applied to the antenna's structural parameters. This is well depicted in Figure 13-2, where the two arms of a six-arm log-periodic antenna is shown. A log-periodic structure can be obtained by taking an appropriate 2D cut of a 3D FI antenna known as a conical screw.⁷ As shown in Figure 13-42, the planar log-periodic antenna is nothing else but a constant ϕ -cut of a conical screw. Following the discussion

FIGURE 13-42 (a) Conical screw, (b) planar log-periodic antenna obtained from the conical screw as $\phi = \text{const}$, and (c) self-complementary two-arm structure with curved teeth

from Section 13.1, it is clear that this structure is not continuously self-scaled with the frequency. However, for a discrete set of frequencies, such that $\log(f_n/f_{n-1}) = \text{const}$, the structure and the bandwidth scale the same way.

Assuming an infinite log-periodic geometry with an infinitesimally precise and fine center region, one observes that the current distributions at two frequencies separated by the ratio $\ln(1/\tau)$, where $\tau = R_n/R_{n+1}$, is the same. This gives rise to the same input impedance with the same period, while the period of radiation pattern is $2\ln(1/\tau)$.⁴ The computed input impedance of a nonplanar log-periodic antenna with 26 elements and a growth rate of $\tau = 0.85$ is shown in Figure 13-43. The variation of the period (as depicted inside the plot) is a consequence of finite antenna size and imprecision in reading out the x -axis values. However, the previously mentioned consequence of the log-periodic growth is clearly demonstrated. As with the spiral antennas, the overall bandwidth is limited by the fine precision of the center region (high end) and finite size (lower end) of the log-periodic radiator.

In this section, our overview includes planar bidirectional and unidirectional log-periodic tooth radiators, as well as end-fire log-periodic dipole and slot arrays. The basic principles of operation, typical performance including multimoding, feeding, and application as reflector feeds are also discussed. For additional reading, see the literature.^{2,4,5}

Planar Log-Periodic Tooth Antennas

Experimental verification of a decade-bandwidth log-periodic FI design was first demonstrated in DuHamel and Isbell's paper, "Broadband Logarithmically Periodic Antenna Structures."⁸ The planar free-standing element, shown in Figure 13-4, is a linearly polarized bidirectional radiator. Very efficient attenuation through the active region composed of several teeth in the neighborhood of a half-wavelength long pair, results in little (if any) observable end effect. The teeth can be of circular or straight/trapezoidal shape with respective antennas showing little difference in performance.³⁹ For bidirectional operation, the

FIGURE 13-43 A consequence of a log-periodic design: depicted is the constant resistance and reactance period when plotted vs. $\ln(f)$.

feed is planar and is realized using a coaxial cable soldered to the metal portion between the teeth (equivalent to the Dyson balun). The coax transitions to the slot in the geometrical center of the antenna aperture. When unidirectional operation of a planar structure backed by a cavity is sought, a vertical balun feed is typically utilized (and also serves as an impedance transformer). The typical impedance at the balanced ports of an antenna with self-complementary geometry is $\sim 160\Omega$. This is slightly lower than the theoretical value of 188.5Ω due to the non-zero metallization thickness, finite features of the feed region, dielectric support (if used), and so on. Lowering the impedance by increasing the metal to slot ratio (deviation from the self-complementary structure), has proven to be very challenging since impedance and pattern variations, both within the period and the bandwidth, are typically significant.

Printed log-periodic antennas are typically designed with two, four, or eight arms. A two-arm planar antenna is linearly polarized, while a four-arm geometry with the phase progression of $\pm 90^\circ$ between the orthogonal pairs of arms, usually implemented with a 90-degree hybrid, is circularly polarized (mode ± 1). Due to the phase ambiguity associated with the excitation of the higher-order modes, more than four arms are needed when circularly polarized multimode operation is desired. The simplicity of the BFN is the main reason why eight-arm geometries are commonly utilized when multimode operation is required. As mentioned, planar sheet log-periodic antennas are typically designed with curved or straight teeth,³⁹ with performance between the two being very similar. The main difference is in the variation of the half-power beamwidth over the operating band. Shown in Figure 13-44 are the averaged beamwidths of four-arm structures when fed to operate in the circularly and linearly polarized modes. The two antennas are self-complementary with the same diameter of 7.5 cm, a growth rate of $\tau = 0.8$, a boom width of $2\beta = 10^\circ$, a tooth swing of $2\alpha = 80^\circ$, and a number of teeth $N = 17$. Consistently, the curved log-periodic has a lesser variation of the 3 dB beamwidth over the wide 9:1 bandwidth. It is important to note that the low-frequency gain and impedance match of the antenna with the straight tooth is slightly better. This is due to the longer length of the teeth and associated square vs. circular antenna aperture. Interestingly, the self-complementary two-arm planar sheet antennas (see Figure 13-42c) typically have several narrow-band VSWR, gain/pattern drop-outs. This can be resolved with the smaller teeth swings and subsequent deviation from the self-complementary principle.

The performance of planar log-periodic antennas is affected by the growth rate $\tau (= R_{n+1}/R_n)$, boom angle 2β , also referred to as the angular separation between the teeth, the angular arm width or swing 2α determining the interleaving between the neighboring arms, and dielectric

FIGURE 13-44 Average 3 dB beamwidth for four-arm planar log-periodic antennas with curved and straight teeth shown in insets when they are fed to operate in circularly (a) or linearly (b) polarized mode

FIGURE 13-45 Computed effects of the boom angle 2β on the broadside co- and cross-polarized mode ± 1 gains of 6-cm diameter four-arm planar log-periodic antennas shown in the inset. Boom angles are $2\beta = 10^\circ$ (a) and $2\beta = 30^\circ$ (b).

constant of the substrate. The structural parameters are as depicted in Figure 13-42. Effects of the boom angle on the performance of a free-standing four-arm planar log-periodic antenna with a diameter of 7.5 cm, $N = 22$ elements, $\tau = 0.82$, and $2\alpha = 80^\circ$ are computed with FEKO, and the results are shown in Figure 13-45. The antennas are fed for circularly polarized modes ± 1 operation. Clearly, an antenna with a narrower boom angle has improved low- and high-frequency operation. Specifically, for the same aperture size, the antenna low-frequency gain, and high-frequency cross-polarization (axial ratio) both improve with the reduced angle 2β . This can be anticipated since the width of the boom affects the length of the teeth and thus the resonant frequency of the lowest active region.

Several planar, printed eight-arm log-periodic layouts, with different lengths of circular teeth (2α) are shown in Figure 13-46. With an appropriately designed mode-forming network, these antennas can produce high-quality multimode and omnipolarized performance with stable modal impedances, consistent patterns, and cross-polarization levels. Typical performance of free-standing structures with an aperture diameter of 6 cm, $\tau = 0.73$, $2\beta = 5^\circ$, and $2\alpha = 40^\circ$ – 70° , for several modes, is shown in Table 13-5. Note that the nominal impedance decreases with the increased mode number, similarly as with multimode spirals. They can be computed using Deschamps's formula (Eq. 13-11). Also, with a more pronounced interleaving between the neighboring arms ($2\alpha \uparrow$), the variation

FIGURE 13-46 Various planar log-periodic eight-arm structures with the arm widths (2α) of 40° (a), 50° (b), 60° (c), and 70° (d)

TABLE 13-5 Averaged Characteristics of Multimode Freestanding Planar, Log-periodic, Eight-arm Structures Shown in Figure 13-46

2α [°]	Mode 1			Mode 2			Mode 3		
	R [Ω]	G [dB]	AR [dB]	R [Ω]	G [dB]	AR [dB]	R [Ω]	G [dB]	AR [dB]
40	300	6.6	0.1	177	4.5	1.0	126	3.1	3.9
50	294	6.6	0.1	158	4.0	1.1	118	2.4	4.0

70	285	5.7	0.1	131	2.6	2.0	91	0.3	17

of both, the resistance, and reactance over the operating band increases. As with other multimode FI antennas, the nominal gain and axial ratio at the elevation of the maximum gain both decrease with increased mode numbers. Increased interleaving deteriorates these two far-field parameters, to the point that structures with $2\alpha \geq 60^\circ$ have several frequency bands where they are linearly polarized when fed for mode 3 operation. For example, for $2\alpha = 70^\circ$, the axial ratio of mode 3 is always greater than 4 dB within the range of this mode's operation.

The increased tooth interleaving contributes to the movement and more pronounced confinement of the radiating region toward the inside of the log-periodic aperture. As a consequence, the radiation from the higher-order modes becomes noticeable via the deteriorated symmetry of the radiation patterns. Shown in Table 13-6 are selected far-field characteristics at 12 GHz for all three copolarized broadband modes. A larger 2α contributes to the symmetric dislocation, or squint, of a mode 1 beam maximum from broadside. The position of the mode 2 and 3 beam maxima remains stable with small and moderate interleaving. The WoW, in general, deteriorates with the increased 2α ; however, for large interleaving, the pattern becomes highly contaminated, as shown in Figure 13-47. Notice the gain reduction due to the miniaturization effects. For multimode operation, these antennas are fed the same way as spirals when a single polarization is needed or as sinuous antennas when dual-polarized operation is required.

Finally, an unusual, yet for some applications desired, performance can be obtained if ambiguous feeding is used. For example, for a four-arm antenna, phase progression of 0° ,

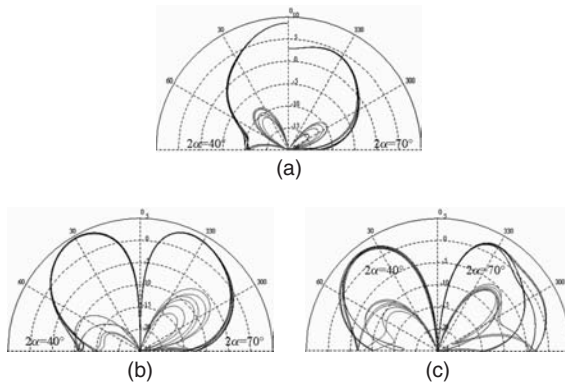

FIGURE 13-47 Modes 1 (a), 2 (b), and 3 (c) radiation patterns for eight-arm planar log-periodic antennas from Figure 13-5. Shown are six overlaid co- and cross-polarized patterns taken with 30° separation in azimuth.

180° , 0° , 180° can produce equally well left- and right-handed circular polarization since this antenna aperture does not have polarization filtering capability as spirals (wrapping direction). As a consequence, the four-arm printed log-periodic antenna radiates a monopole-like horizontally polarized pattern along the symmetry planes of the arms and a vertically polarized pattern along the planes between the arms. The total gain pattern is fairly omnidirectional. Shown in Figure 13-48a and b are computed three-dimensional linear gain patterns at the midband frequency obtained with FEKO. Also shown in Figure 13-48c are overlaid co- and cross-polarization patterns at six discrete frequencies over a 4:1 band in two constant azimuthal cuts and in Figure 13-48d, a constant elevation cut at $\theta = 38^\circ$. The radiation patterns are very consistent over a wide frequency range, with the polarization sense changing every $\phi = 45^\circ$. A deep null at broadside, with max gains around $\theta = 38^\circ$, good cross-polarization, and matched gain values close to the gain of a half-wave dipole are the main properties of this antenna. This unconventional frequency independent log-periodic antenna is well matched throughout the operating band.

Non-Planar Log-Periodic Tooth Antennas

Efficient unidirectional operation can be achieved by folding the planar arms, i.e., by reducing the angle between the axes of the arms⁴ or by projecting the planar log-periodic structure on a cone.⁴³ The latter is more complicated to design, and since they perform similarly, the former will not be described further. The angle between the folded arms is denoted ψ in Figure 13-49. For a planar configuration $\psi = 180^\circ$, note that the teeth are straight, with the relative width computed as $\varepsilon = r_N/R_N$ (typically $\varepsilon > \tau$). Folding eliminates the need for lossless reflective (band-limited) and/or lossy absorptive (broadband) cavities and typically yields about a 2–2.5 dB increase in forward gain when compared to the free-standing (or absorptive cavity-backed) antenna. Additionally, smoother frequency response can be obtained with fewer teeth, and simpler feeding can be designed. To reduce the antenna weight and windload, the solid metallic arms of a free-standing structure can be replaced by a thin metallic wire or strip that outlines the arms.³⁹ Changes in impedance and pattern are minimal since the current is concentrated along the edges of the original geometry.

FIGURE 13-48 Computed 3D gains G_ϕ (a) and G_θ (b) at midband for a four-arm log-periodic planar tooth antenna with overall phase progression between the arms of 720° . Also shown are constant azimuth (c) and constant elevation (d) cut co- and cross-polarization patterns for six discrete frequencies over a 4:1 frequency range.

FIGURE 13-49 Trapezoidal-tooth log-periodic antenna (after R. H. DuHamel and F. R. Ore³⁹ © IEEE 1958)

Due to the small variations of antenna impedance and pattern over wide frequency ranges, these antennas are commonly used as wideband feeds for reflectors.⁴⁴ They can be fed with an infinite balun, thus eliminating the need for the crisscross feeders and significantly simplifying their construction. The only major disadvantage is the phase center movement versus frequency. A NEC wire model of a 1–18-GHz design is shown in Figure 13-50a. A total of 26 resonant dipole pairs (elements) are distributed along the boom with the growth rate of $\tau = 0.85$. Arms are subtended over an angle of $\psi = 5.6^\circ$. The boom width is $2\beta = 2.2^\circ$, while the arm width is $2\alpha = 33.4^\circ$. The feed is at the high frequency end, with a distance between the arms of 1.5 mm.

The nominal input resistance of this antenna is about 95Ω , and it can be tuned by varying the distance between the arms at the feed location. Shown in Figure 13-50b is the computed VSWR with respect to 50Ω and the antenna nominal impedance. When a broadband impedance transformer is used, this antenna can be matched for the $\text{VSWR} < 1.5:1$ throughout the designed frequency range. A direct 50Ω feed will still produce an adequate match with $\text{VSWR} < 2.3:1$ throughout the operating band.

The antenna HPBW and gain are shown in Figure 13-51. The E -plane variation throughout the 18:1 frequency range is about $\pm 5^\circ$, while the H -plane beamwidth changes about $\pm 14^\circ$ around the averaged value. Notice that the period varies with the logarithm of frequency. For many applications, the 10-dB beamwidth is important, particularly when used as the feed for a reflector antenna. The log-periodic antenna discussed in this paragraph has 10-dB E -plane and H -plane beamwidths in the ranges 99° – 108° and 130° – 203° , respectively.

It is interesting to note that the wider H -plane beam (and associated deviation around the nominal value) can be tuned by changing the angle ψ . By increasing the angular separation between the arms, the beam becomes narrower in the H -plane. At the same time, the E -plane beamwidth is only slightly changed. Thus, if needed, an antenna with very similar patterns in the E - and H -planes can be obtained. However, the drawback is reduced front-to-back ratio. Note also that directivity is increased due to the smaller H -plane beamwidth, and it can be further enhanced by increasing the growth rate τ and optimizing angle ψ . The nominal values for the 3-dB beamwidths in E - and H -planes as a function of ψ are shown in Table 13-7.

The nominal impedance of non-planar log-periodic tooth antennas can be tuned by changing the distance between the arms. Reduced spacing increases the capacitance of the

FIGURE 13-50 Sketch of a 26 element 1–18-GHz non-planar log-periodic tooth antenna with the following parameters: (a) $\psi = 5.6^\circ$, $2\alpha = 33.4^\circ$, $2\beta = 2.2^\circ$, $\tau = 0.85$, and (b) computed VSWR for 50 and 95Ω match

transmission line, and thus its characteristic impedance. When the angle between the arms is maintained, the far-field is not significantly changed. The variation of input resistance and reactance for various spacings between arms is shown in Figure 13-52. The antenna parameters are $N = 26$, $\tau = 0.85$, $2\beta = 2.2^\circ$, $2\alpha = 33.4^\circ$, and $\Psi = 5.6^\circ$.

Log-Periodic Dipole Antennas

The log-periodic dipole array (LPDA) antenna was the first FI antenna that immediately after conception made a huge impact on both commercial and military applications throughout the world. Although Carrel's studies have provided a theoretical and experimental foundation for log-periodic dipole antennas,⁴⁰ the concept was first proposed by Isbell,⁴⁵

TABLE 13-7 Averaged Characteristics of a 1-18 GHz Non-planar Log-periodic Tooth Antenna for Various Angles Between the Arms (For this 26 element, log-periodic antenna $2\alpha = 33.4^\circ$, $\tau = 0.85$, and $2\beta = 2.2^\circ$)

FIGURE 13-52 Computed input resistance (a) and reactance (b) versus frequency for a log-periodic antenna with $\psi = 5.6^\circ$, $2\alpha = 33.4^\circ$, $2\beta = 2.2^\circ$, and $\tau = 0.85$. The variable is the distance between the booms (arms).

who made the following modifications to the structure he previously conceived with DuHamel:

- Arms of the tooth structure are folded, and their axes are made parallel. This corresponds to the limiting case of the angle $\psi \sim 0^\circ$.
- The width of the teeth $R_N - r_N$ is kept constant throughout the antenna structure.
- Planar circular teeth are replaced by straight wires with uniform cross-section.
- The apex angle of an embedded cone (in the basic conical screw geometry that, as discussed earlier, is the foundation for the planar sheet) approaches the limit 0° . In other words, the supporting booms are straight rods typically with rectangular cross-sections.

As a result of these modifications, a log-periodic wire dipole antenna emerged, most frequently used worldwide as a receiving antenna for terrestrial VHF/UHF radio and television (see Figure 13-53). The antenna consists of two in-plane sets of crisscrossed monopoles whose lengths and separations are related via the growth rate τ . The alternating feeding

FIGURE 13-53 Schematic diagram of a log-periodic antenna. The three dashed lines indicate typical locations of electric ground planes between each pair of dipoles.

is required to achieve the backward end-fire radiation in the direction of the small dipole pairs. The currents on the consecutive monopoles in the transmission line region are in the opposite direction, thus contributing little to the overall radiation. However, the capacitive loading of open-ended monopoles produces the slow-wave effects in this region (typically $v = 0.6c$). The active region width depends on the antenna structural parameters (τ , α), and it occurs where the monopoles are about $\lambda/4$ long. With a properly designed antenna, the radiation losses in this region are large (20 dB or higher), so the residual currents are small and can be neglected. If the monopoles on each boom are directly connected such that the two-wire line is the feeder for the log-periodic dipole pairs, radiation would occur in the forward end-fire direction. It is clear that the effects of the non-resonant, capacitive dipoles in the transmission line region and the dipoles past the active region will be such that the far-field contamination would be significant. A typical performance of a well-designed log-periodic dipole antenna with $\tau = 0.95$ is characterized in Figure 13-54.

A systematic design of log-periodic dipole antennas was also provided by Carrel, and with some modifications can be found in many antenna textbooks.^{5,6} It is important to note that the scaling principle does not need to be applied to all structural parameters of this antenna, i.e., the boom tube diameter and the boom spacing can and usually are kept constant. Their effect on the antenna performance is minimal. To describe the structure, and eventually design the log-periodic dipole antenna, we are presented with two out of three important structural parameters: growth rate τ , angle 2α , and spacing factor σ defined as the normalized distance between a dipole and its closest, smaller dipole. The normalization is performed with respect to the length of the longer dipole. Along with the desired bandwidth, any two of these parameters are needed to describe the antenna structure. The spacing factor can be computed as

$$\sigma = 0.25(1 - \tau) \cot \alpha \quad (13-15)$$

The constant directivity counters, as originally given by Carrel⁴⁰ but corrected by Butson and Thompson,⁴⁶ as functions of τ and σ , are plotted in Figure 13-55. The feeder impedance of 100Ω and the ratio of monopole length to the width of 125 are taken as constants (see the literature^{47,48} for more extensive study).

FIGURE 13-54 Computed average gain and 3-dB beamwidth in E- and H-planes of a log-periodic dipole array with $\tau = 0.95$

FIGURE 13-55 Constant-directivity contours in decibels versus τ and σ . Optimum σ indicates maximum directivity for a given value of τ (after R. L. Carrel⁴⁰ © IRE 1961).

As discussed, the log-periodic dipole antenna is fed at the high-frequency end, thus achieving end-fire radiation along the direction of the smaller monopole lengths. A two-wire transmission line can be used for direct excitation of the monopoles placed at the booms. However, a much simpler method of feeding is to use a coaxial cable inside one of the hollow booms, and at the high-frequency end attach its outer conductor to the host boom and the inner conductor to the opposite boom tube. This is a broadband balanced feed and to some extent resembles an infinite balun. When used for terrestrial television, the coax is usually 75Ω and a 4:1 impedance transformer is used at the TV set to convert to 300Ω . A drawing of the coaxial feed is shown in Figure 13-56.

Log-Periodic Folded Slot Antennas

Thorough coverage, including experimentally obtained findings regarding log-periodic folded slot antennas, was in Chapter 14 of the previous edition of this book. Shown in

FIGURE 13-56 Coaxial feed arrangement for a log-periodic dipole antenna

FIGURE 13-57 Log-periodic folded slot antennas with growth rate (τ) of 0.8 (a), 0.85 (b), and 0.9 (c)

Figure 13-57 are several log-periodic folded slot antennas designed for the same frequency range but with three different growth rates and numbers of arms. The shading represents slots etched in a (typically) copper metallization of a thin low-dielectric constant and low-loss substrate. The parameters for these antennas are determined using the steps described by Carrel.⁴⁰ In this case, the designed bandwidth is 4:1, so the number of arms is $N = 9, 12, 17$ for $\tau = 0.8, 0.85, 0.9$, respectively. Between the folded slots are “phasing slots” needed to provide the proper phase delay necessary for end-fire radiation.^{4,49} As with other log-periodic antennas, $\tau = L_{i+1}/L_i$ is the growth rate, and it determines the period of logarithmic repetition in electrical performance. To uniquely specify the antenna geometry, one needs to define the growth rate τ and either σ or α .

As stated earlier, the presence of the phasing slot is critical for end-fire performance of this antenna. If the phasing slot is not used, the growth rate has to be close to 1 in order to reduce gain dropouts and other anomalies in the radiation pattern. It is generally accepted that the radiation patterns are less sensitive for slot lengths when they vary between $\alpha/3$ and 1.5α . Maximum gain for two different lengths of phasing slots is computed using Ansoft Designer and compared with the case without slots (see Figure 13-58).

Three-dimensional radiation patterns for the cases with and without the phasing slot are shown in Figure 13-59. The narrowband gain dropouts, as well as deteriorated front-to-back ratio, multilobes, and so on, are present when the phasing slot is not used. With the phasing slot, the near- and far-field characteristics of the antenna vastly improve. The simulations have shown that the slot lengths around 1α produce the best antenna performance. Measured radiation patterns for a folded slot array are shown in Figure 13-60.

A folded slot log-periodic antenna is most often fed using a coaxial cable, as shown in Figure 13-61. This feed is very similar to an infinite balun, and the parameters of the slot can be easily adjusted for good match. A microstrip feed with a broadband via transition, or a coplanar waveguide line continuing into the log-periodic slot formation, can be easily integrated with this antenna. For conformal integration, the antenna is placed above an absorber-backed cavity.

Log-Periodic Antennas as Reflector Feeds

Log-periodic antennas have been successfully implemented as feeds for reflector antennas.^{44,50,51} The major advantage of these antennas is that they can be designed for a relatively constant impedance and pattern bandwidth, characteristics desired for reduced mismatch and amplitude/phase illumination losses. The major disadvantage is that the phase center moves with frequency—similar to a conical spiral feed. By considering the respective theories of operation, the variation of the phase center with frequency (wavelength) with respect to the tip of (high-frequency end) the conical spiral and non-planar log-periodic can be computed as in Eq. 13-16 and Eq. 13-17, respectively. This variation results in the defocusing losses observed as the reduced gain of the reflector system.⁵²

$$z_{\text{spiral}} = (\lambda/2\pi) \cot \alpha \quad (13-16)$$

$$z_{\text{log-periodic}} = (\lambda/4) \cot \alpha \quad (13-17)$$

Since reflector antennas with the log-periodic feeds are aimed for broadband operation, the positioning of the feed with respect to the focal point of the reflector dish is very important. Before delving into the analysis, note that the phase center variation of the log-periodic from Section 13.3, “Non-Planar Log-Periodic Tooth Antennas,” is somewhat larger than that of the spiral (see Figure 13-62). One can control this spread by choosing an appropriate angle 2α . Sometimes, this parameter varies along the antenna axis. This is done to reduce the antenna height and minimize defocusing losses.

For a specific log-periodic design, the feed position with respect to the reflector’s focal point can be chosen in different ways. In the forthcoming analysis, it was assumed that the defocusing losses are the same at the lowest and the highest frequency of the desired bandwidth. This is the most common approach, and it can be easily shown that the distance between the tip (apex) of the log-periodic feed and the reflector focal point is

$$\Delta = \frac{f_l z_l + f_u z_u}{f_l + f_u} \quad (13-18)$$

FIGURE 13-62 Comparison of the phase center movement in z -direction versus frequency for conical spiral and non-planar log-periodic feeds designed to operate over the same bandwidth

where z_l and z_f are computed from Eq. 13-17. They represent the locations of the phase center at the lowest and highest frequencies of operation, respectively. Sometimes the position of the feed is chosen such that the defocusing losses are minimized at the highest end of the operating band. In this way, the somewhat larger resistive losses associated with the feeder are compensated for. In applications where high quality performance is required only over a set of narrow (but instantaneous) bands, the location of the feed can be set to minimize the loss at the most critical band.

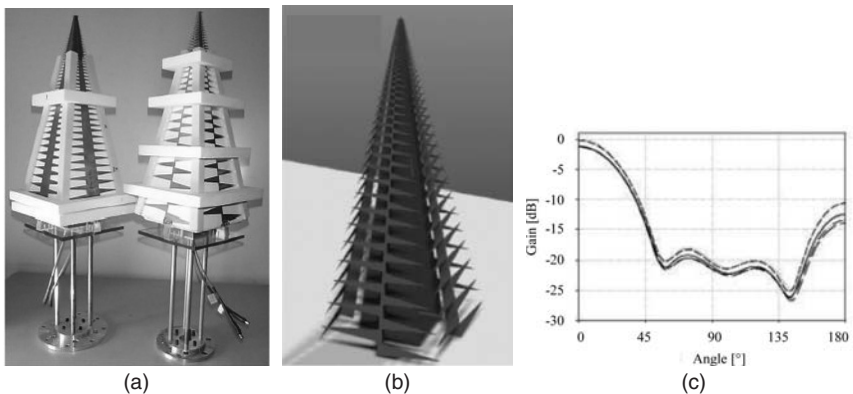

The loss budget of a 10:1 broadband log-periodic tooth-feed for several reflector F/D ratios is shown in Table 13-8. To reduce the losses with an enlarged F/D ratio, the growth rate τ must be increased. The number of elements must also be increased to retain the same bandwidth for optimum illumination. As expected, for lower F/D ratios, the phase error loss (PEL) is increased. Amplitude taper loss (ATL) is also high for low F/D as the feed is too directive and under-illuminates the reflector. The spillover losses (SPL) increase as the F/D increases, and they are the dominant loss mechanism for $F/D > 0.4$. Since the maximum LP directivity is about 10 dB, the reflector becomes over-illuminated, and the ATL is very low. Cross-polarization loss decreases for larger F/D , but primarily due to the more pronounced effects of the feed pattern missing the reflector, thus being counted as spillover loss. Minimum aperture loss is about 2.2 dB, and it is obtained for $0.3 < F/D < 0.4$. For this analysis, the feed was positioned for equal losses at the high and low end of the band. For extremely wide bandwidths, 2α can vary along the feed axis, i.e., it is increased at the lower frequencies to reduce PEL in favor of higher SPL.

High-performance dual-polarized log-periodic feeds with $\psi = 20^\circ$, $2\beta = 3.3^\circ$ and 0.67° , $\tau = 0.975$ and 0.96 , designed for operation over 0.5–11-GHz band are shown in Figure 13-63.⁵⁰ Averaged elevation radiation patterns for five frequencies log-periodically distributed over one period τ are also shown. The patterns are very uniform, with the max gain variation of

only 0.75 dB, the first sidelobe level around 18 dB, and a front-to-back ratio of about 13 dB. Measured cross-polarization was around 15 dB within the 13 dB power contour of the beam. By decreasing the boomwidth and growth rate from 3.3° to 0.67° and 0.975 to 0.96, respectively, cross-polarization improved by about 10 dB. The pyramidal shield was added to allow for an undisturbed illumination pattern when the amplifiers are added to the feed point (for reduced feedline losses and their adverse effect on the receiver temperature).

13.4 DUAL-CIRCULARLY POLARIZED ANTENNAS

Antennas capable of generating an arbitrary polarization over a wide frequency range have been utilized in many applications including electronic warfare, radio astronomy, and remote sensing, just to name a few. Any combination of two orthogonally, linearly polarized radiators with a feed network designed to support different phasing combinations can be utilized for this purpose. A schematic of a feed network utilized to generate left- and right-hand circular polarizations with two sets of orthogonally oriented arm pairs is shown in Figure 13-64. The phase progressions between neighboring arms are 0° , 90° , 180° , 270° (-90°) for RCP and 0° , -90° , -180° , -270° (90°) for LCP. As shown earlier, these two sets of phases contribute to the two ± 1 modes, both having a broadside main beam. Multimode, dual-polarized excitation schemes have also been devised, and they are typically used for monopulse direction finding. For example, a BFN comprised of nine 3-dB magic T's and two 90° hybrids was designed for dual-polarized 2–12-GHz operation in conjunction with an eight-arm monopole log-periodic radiator.⁵³ The stable response with minimum amplitude and phase misbalances over wide bandwidths, as well as the high frequency losses, impose a major challenge in the design of these feeds. Due to their aperture that enables dual-circularly polarized operation (no polarization filtering as in a spiral antenna), the planar embodiments of these antennas are fabricated with an absorber-filled cavity. Any reflective backing, and consequent polarization nondiscriminative coupling to the feeds, severely degrades their impedance and pattern performance. Finally, it is important to note that the cost of the BFN is the major reason for their limited use.

In this section, we discuss several dual-polarized frequency independent configurations with multiple or single feeding arrangements. Specifically, inside-outside fed spirals, modulated armwidth spirals, and sinuous and folded spiral antennas are described. Important structural/geometrical features utilized to realize the dual-polarized performance are outlined. The typical performances and the effects of various parameters have been given. Multiarm dual-polarized and multimode planar log-periodic antennas are discussed in the previous section and will not be addressed here.

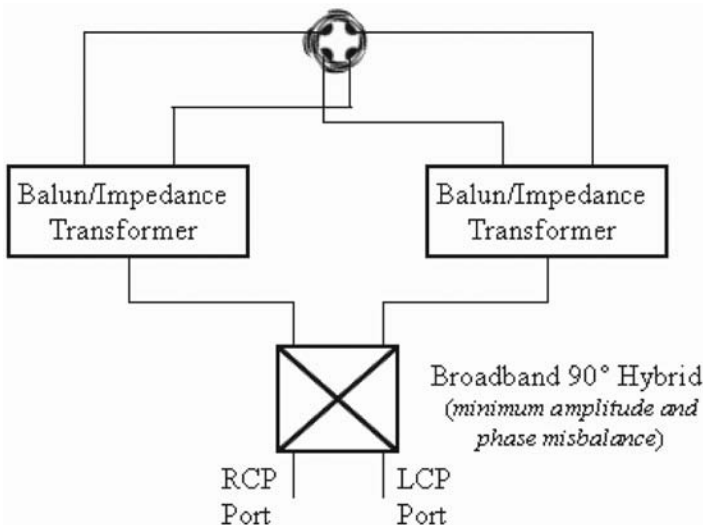

FIGURE 13-64 Circular-polarization feed network for a four-arm, dual-circularly polarized antenna

Inside-Outside Fed Spirals

A spiral can be fed from either the inner ports, outer ports, or both simultaneously. Since the spiral polarization is determined using the right-hand rule, a counterclockwise-wound spiral fed from the inside radiates RCP. The same spiral, when fed from the outer ports, radiates LCP. When access to the spiral is provided from both sides, the antenna becomes a broadband dual-polarized radiator. Feeding from the outside has the additional advantage of allowing ample room to provide impedance matching networks. Stripline or microstrip transitions can be designed to match to 50Ω , and broadband matching for multiple modes can be readily achieved. A major disadvantage of outside feeding is that the highest order mode of excitation will radiate first, thus limiting the effective bandwidth of this type of antenna. To increase the bandwidth, more arms must be added, thus increasing cost due to a more complicated and expensive beamforming network. A higher order, for this structure sometimes also called *parasitic*, mode-free dual-polarized bandwidth of inside-outside fed spirals can be found using expression

$$B \leq \frac{N+2}{2(M_h + \pi\Delta)} \quad (13-19)$$

where B is the bandwidth ($f_{\text{high}}/f_{\text{low}}$), N is the minimum number of arms, M_h is the highest order mode used, and Δ is the width of the radiation band (typically $\Delta = 0.18$).

Computed bandwidths for multimode operation of inside-outside fed spirals are shown in Table 13-9. To obtain an octave bandwidth dual mode and dual polarization performance at least eight arms are required (1.95:1 bandwidth). For a four-arm spiral, the dual-mode dual-polarization bandwidth is only about 17 percent. By relaxing the requirements for the gain and WoW, the bandwidth will increase.

When the spiral is fed from outside, a continuous conductive ring is required to keep the coaxial feed outside conductors at the same potential. This can be accomplished by using a mounting flange just outside of the spiral cavity. A microstrip or stripline is used to transform the impedance from 50Ω (at the outside port connectors) to match to the spiral arm ending width. This works well for small growth rates toward the spiral perimeter. A drawing of an outer microstrip transition is shown in Figure 13-65.

Measured radiation patterns for an inside-outside fed two-arm loosely wound slot spiral¹⁴ are shown in Figure 13-66. The antenna was fed with a dual-infinite balun feed at both feeding ports. The impedance matching is achieved with the high-impedance large circular element terminating the very narrow, low impedance slotlines constituting the spiral arms. Overlaid are 36 azimuthal cuts taken at frequencies of $1.5f_0$ and $2.5f_0$, where f_0 denotes the

frequency associated with the operational wavelength equal to the physical circumference of the antenna. Dual-polarized performance with the broadside beam is clear from the figure. Also, the lower frequency pattern is very symmetric, with very little difference between the two feeds. The higher frequency pattern shows significant degradation in both the symmetry (WoW) and the cross-polarization level. As discussed previously, this is because of the significant attenuation due to radiation through the mode 3 ring. At higher frequencies, the beam squints off center and the mode 3 radiation dominates. A measurement of the far-field phase progression at a constant elevation angle (typically greater than 30°) reveals that for the outside fed spiral, the phase progression of 1080° , associated with mode 3, starts at frequencies close to $3f_0$. For an inside feed, this transition occurs at about $4f_0$ (with this lower efficient slot spiral).

Measured mode content of the radiation pattern of the two-arm inside-outside fed spiral taken at $\theta = 38^\circ$ is shown in Figure 13-67. For the outside feed, the mode 3 radiation starts to dominate the far-field above $3f_0$, while the cross-modal discrimination of greater than 20 dB is seen for frequencies $f > 2f_0$. Note that this slot spiral is not a very efficient radiator when fed inside, thus resulting in even higher mode 3 content than typically measured with well-designed printed spirals.

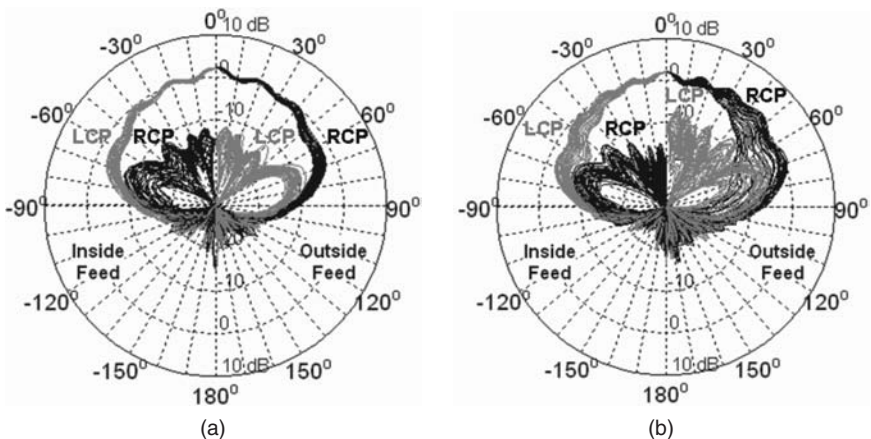

FIGURE 13-66 Measured radiation patterns of a two-arm inside-outside fed spiral taken at $1.5f_0$ (a) and $2.5f_0$ (b). Overlaid are 36 constant ϕ cuts of left- and right-handedness.¹⁴

Modulated Arm Width Spirals

The MAW spiral¹⁹ was the first center-fed spiral antenna with multi-octave dual-polarized operation. The MAW spiral incorporates arm impedance modulations for creation of bandstop regions. A bandstop, otherwise known as a *band-reflect region*, utilizes a series of half wavelength high/low impedance sections ($1/4$ wavelength each), which provide a broadband method for reflecting the spiral's traveling wave, thus in turn generating the backward oppositely polarized wave. These reflected currents generate modes similar to the outside fed spiral described in the previous section, but without the over-moding limitations. The MAW spiral bandwidth has the same limits as the regular spiral, i.e., the highest frequency is determined by the fineness of the central region, and the lowest limit is determined by the diameter of the spiral. Due to its ability to support both forward and backward waves in dominant active regions, multimode operation can be achieved by increasing the number of arms. For a MAW spiral to operate with m useful modes, the minimum number of arms is $N = 2m + 1$. Thus, for single mode dual-polarized operation, the MAW must have at least three arms. An eight-arm printed/wire MAW is shown in Figure 13-68. Narrow lines represent the high-impedance sections, while the wide strips correspond to the low-impedance sections.

FIGURE 13-68 An eight-arm MAW spiral. The forward wave is RCP; the reflected wave is LCP.

The band-reflect region is set at the circumference of $N/2$ guided wavelengths, where N is the number of arms. A four-arm MAW will reflect the currents at the 2λ circumference, thus limiting this antenna to single mode operation, but preserving the dual circularly polarized capability. To correlate the port phasing with the performance, assume a counterclockwise wound four-arm-printed MAW spiral. This antenna (center-fed) will produce RCP mode 1 radiation for feed phasing vector $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$. Now, if you excite the feed ports with the vector $\{0^\circ, -90^\circ, -180^\circ, -270^\circ\}$, this corresponds to the mode -1 for the RCP spiral. This phase progression is identical to the phase vector $\{0^\circ, 270^\circ, 540^\circ, 810^\circ\}$, which creates a $3 \times 360^\circ$ far-field progression on a $\theta = \text{constant}$ cone and represents the mode 3 phase vector. Thus, the forward traveling wave will pass the mode 1 region without radiating, arrive at its band-stop region at the 2λ circumference, undergo reflection and become a backward (reflected) traveling wave traveling back toward the spiral's center. At the 1λ circumference, phasing is correct to radiate mode -1 and a LCP mode pattern is generated.

The band-reflect section is not required in the low-frequency region. For example, an eight-arm 6-cm diameter MAW will have good mode 2 radiation at 3.3 GHz; however, the mode 4 band reject ring need not exist since the spiral will not radiate mode -2 ($m6$). Since a reflection from the end of the arm is desired, end-loading should not be used for MAW spirals. Also, the inner band reject region need not exist unless it is required for rejecting the highest frequency of the lowest mode. Radiation patterns for forward (RCP) and reflected (LCP) modes 1, 2, and 3 of an eight-arm exponential MAW with EXP = 1.5 taken at 12 GHz are shown in Figure 13-69a. The antenna has 6-cm diameter and the modulation ratio is 11. Thicker lines represent the RCP gain. The main difference is in the deteriorated cross-polarization levels associated with the reflected modes 2 and 3. The difference in mode 1 is insignificant. Overall, the far-field consistency of all modes is acceptable, with small WoW and excellent axial ratio for modes 1 and 2 and a somewhat deteriorated value for mode 3. The input resistance for all modes is given in Figure 13-69b. As with spirals, the modes ± 1 have the highest value of nominal impedance, with very little difference between the forward and reflected modes. Due to the presence of high/low impedance sections, the resistance has highly oscillatory behavior. The nominal mode impedances for forward and reflect modes 1, 2, and 3 are 287Ω , 160Ω , and 127Ω , respectively. This spread of modes and relatively large span of resistance values (from 72Ω to 325Ω) makes beamformer design very challenging. As with spirals, the higher-order modes turn on at the higher frequency.

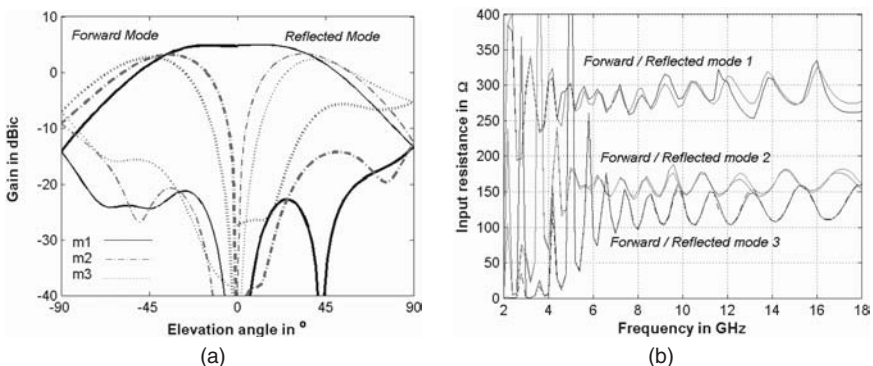

FIGURE 13-69 Radiation patterns for forward and reflected modes of (a) an eight-arm MAW and (b) input resistance vs. frequency. Forward and reflected modes 1, 2, and 3 are considered.

The most important parameter for the performance of a MAW is the *modulation ratio*. It is defined as a ratio between the consecutive wide and thin sections. With an Archimedean MAW, this ratio remains constant throughout the antenna aperture. However, the tightly wound, exponential MAW is typically used due to reduced ringing. Typically, the modulation ratio should be in the 4 to 15 range for good dual-circular polarization of the radiation pattern. A computational study with GNEC is used to demonstrate the effects of this parameter on the performance of a four-arm exponential MAW with $\text{EXP} = 1.5$. The antenna diameter is 7.5 cm, and an ideal beamformer with zero amplitude misbalance and correct phasing is assumed. Modulation ratios in the range from 1 (classical self-complementary equiangular spiral) to 10 are considered. In practice, the fine precision of the feed region and etching finesse are also important to consider. The subset of six different MAWs used in this study is shown in Figure 13-70.

Effect of the modulation ratio on the average cross-polarization level over 2–18GHz and elevation angles $\theta < 30^\circ$ is shown in Figure 13-71a. While the forward mode sees very little variation in the axial ratio, remaining very low throughout the considered range of values, the polarization purity of the reflected mode undergoes significant improvement with increased modulation ratio. Similar conclusions can be drawn for the consistency of the radiation pattern for both modes. Shown in Figure 13-71b are the averaged values for the HPBW over the entire 2–18GHz range, along with their minimum and maximum bounds (associated with the azimuthal variations) plotted against the modulation ratio. While no significant effects are observed with the forward wave, the reflected mode starts to converge when the modulation ratio becomes greater than 8.

Shown in Figure 13-72 are averaged broadside gains from 4–18GHz and WoW at $\theta = 30^\circ$ from 2–18GHz. Forward mode pattern symmetry is very good regardless of modulation ratio. Reflected mode symmetry is somewhat worse, but the average WoW is still about 1 dB over the band. Gain for the forward modes is constant at 5.7 ± 0.3 dBic for all modulation ratios. As expected, reflected mode gain is highly dependent on the modulation ratio. Modulation ratios of at least 8 are required for gains approaching those of the forward modes (within 1 dB).

Sinuuous Antennas

The traditional sinuous antenna is a broadband, log-periodic structure with $N \geq 4$ arms composed of arcs and bends and whose low- and high-frequency operation limits, when significantly interleaved, are determined by the outer and inner diameters of the antenna, respectively.^{4,41,42} As shown in Figure 13-73, the sinuous configuration is fully depicted by the angles α , or angular span of defining sinuous curve, and δ , or rotation angle needed to outline the sinuous arms, as well as the log-periodic growth rate of τ . If any of these three defining parameters is varied from cell to cell, a quasi-log-periodic sinuous structure is obtained.

Most sinuous antenna research has been devoted to the planar four-arm printed/wire geometries. Since a free-standing antenna radiates bidirectionally, an absorptive cavity or conical projection of the sinuous structure is required for unidirectional operation. Though a lossy cavity backing reduces the antenna efficiency, it is the preferred approach for conformal and flush-mounted applications. Reflective metal backings integrated with the aperture as an empty cavity or cavity with vertical wall-absorber liners, cause strong coupling

into the sinuous feeds and severe mismatch. Additionally, contamination of the radiated far-field occurs as characterized with the gain drop-outs, increased axial ratio, and WoW. Several commercially available sinuous antennas with different mounting arrangements, including lenses, are shown in Figure 13-74.

A tightly coupled sinuous antenna whose arms have significant interlacing—for example, $1.25 \times 2(\alpha + \delta) > 360/N$, where 1.25 denotes the interlacing parameter—has approximately the same frequency limits as a spiral antenna; that is, the sinuous antenna needs to be N wavelengths in circumference to support efficient mode N radiation. In practice, for a given low-frequency limit, the circumference of the sinuous antenna should be increased by a certain value, typically $\lambda/2$, to account for the finite width of the radiation region. Excitation of the sinuous antenna, when operated in a circularly polarized mode, is also identical to the feeding of a spiral antenna. One exception to this similarity is that the sinuous antenna is dual-polarized from a single feed and has

FIGURE 13-74 Sinuous antennas (Courtesy of L-3 Communications)

additional capabilities and, unfortunately, additional restrictions. Due to the alternating clockwise (CW) and counter-clockwise (CCW) wrapping senses in each arm and the inability of the aperture to perform polarization filtering, the sinuous antenna with N arms can support $(N - 1)/2$ broadband modes. Although the overall number of modes on an N -arm sinuous antenna is one half the number of modes on a comparable N -arm spiral, their radiation patterns are very similar. Only mode 1 has a broadside radiating component and all other modes have a null on broadside, with each higher-order mode peaking further from the null. Note that each of the modes on a sinuous antenna can be obtained in both left- and right-handed circular polarization (RCP, LCP). If M modes of operation with the same polarization are desired, an $N = 2M + 1$ arm sinuous antenna is needed. These modes will be excited if equal amplitudes and phase progressions of $-360^\circ nm / N$ are provided at the arm feeds (taken in the CW direction). Here, n is the arm number ($n = 1, 2, \dots, N$), m is the mode number ($m = 1, 2, \dots, \lfloor (N-1)/2 \rfloor$), and N is the total number of arms. If the highest-order mode that can be supported by an arbitrary N -arm sinuous antenna is m ($m > 0$), the following modes can coexist: $-m, -m + 1, \dots, -1, 1, \dots, m - 1, m$, with positive modes denoting the RCP and negative modes denoting the LCP, respectively. Therefore, at least $N = 5$ arms are needed to obtain dual-mode operation, which is important for monopulse direction finding.

To further understand the relation between the number of sinuous arms and the modal spectrum supported by its structure, an arbitrary $N = 4$ arm sinuous geometry will be utilized. A corresponding four-arm CCW wound spiral antenna will support broadband RCP modes M1: $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$, M2: $\{0^\circ, 180^\circ, 360^\circ, 540^\circ\} \equiv \{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$, and M3: $\{0^\circ, 270^\circ, 540^\circ, 810^\circ\} \equiv \{0^\circ, -90^\circ, 180^\circ, 90^\circ\}$ with the phase progression (in the CW sense) denoted in brackets $\{\}$. A four-arm sinuous antenna has spiral segments capable of radiating both senses of circular polarization, thus when the mode 2 phase progression is provided at the arm ports $\{0^\circ, -180^\circ, -360^\circ, -540^\circ\} \equiv \{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$, the aperture cannot differentiate between it and the mode -2 phase progression $\{0^\circ, 180^\circ, 360^\circ, 540^\circ\} \equiv \{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$, so the radiating region radiates the mixture of modes 2 and -2 .⁵ The mode 3 phase progression is $\{0^\circ, -270^\circ, -540^\circ, -810^\circ\}$, and the RCP four-arm spiral supports its efficient and broadband radiation (provided the circumference is greater than three wavelengths). If the same phase progression is provided to the sinuous antenna, we notice that it is equal to the progression of $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$, which is identical to that of the mode -1 . This mode will be excited first (it radiates from the area the traveling wave encounters before arriving at the mode 3 radiating region) and little energy will be left for mode 3. Thus, as stated previously, for dual-mode operation, a sinuous antenna must have at least five arms, with unique and unambiguous phase progressions for mode 2 $\{0^\circ, -144^\circ, 72^\circ, -72^\circ, 144^\circ\}$, and mode -2 $\{0^\circ, 144^\circ, -72^\circ, 72^\circ, -144^\circ\}$.

Six or eight arms are generally used due to beamformer limitations. An eight-arm sinuous antenna, shown in Figure 13-75, has the additional benefit of supporting a third mode, or modes ± 3 . Typical radiation patterns for the three modes radiated from an eight-arm sinuous antenna are shown in Figure 13-76. Clearly, the previously discussed characteristics of modes 2 and 3 as well as a very good cross-polarization at beam-peak angles are obtained with this structure.

With good quality sinuous designs, currents decay rapidly past the radiation region, and the radiated power of higher-order modes ($m + N, m + 2N, \dots$ and $m - N, m - 2N, \dots$, etc.) is low. Thus, the azimuthal pattern symmetry is usually excellent. As with equiangular spirals, the modal decomposition of the radiated far-field pattern can show the level of modal isolation for each of the sinuous modes. For example, the radiation pattern of mode 1 of an eight-arm sinuous antenna is decomposed into the higher order, contaminating modes. The cross-modal difference with respect to the dominant mode 1 of a first few, most significant modes is shown in Figure 13-77. The cross-modal difference is better than 30 dB for both higher-order modes supported by this antenna (modes -7 and 9),

FIGURE 13-75 An eight-arm self-complementary sinuous antenna

while mode 5 is virtually not excited. Since radiation from the dominant mode region is very efficient, end terminations are rarely needed, as opposed to spirals where some form of lossy arm termination is normally used. Also, for similarly sized and designed feed regions, the high-frequency radiation of a sinuous antenna is usually superior to that of a spiral.

The nominal modal impedance of a free-standing, self-complementary, N -arm printed sinuous antenna can be computed using Deschamps formula Eq. 13-11. Impedance variations from these nominal values can be significant, typically exceeding 2:1 for the mode ± 1 operation. Higher-order modes usually have smaller absolute impedance variations, but these deviations are still greater than their spiral counterparts. If necessary, a spiral can be used in the sinuous interior as a tapered matching section. Typical characteristics of

FIGURE 13-76 Radiation patterns for the M1 (a), M2, and M3 (b) of an eight-arm sinuous antenna

FIGURE 13-77 Higher-order mode gains relative to the gain of M1 for an eight-arm sinuous antenna

self-complementary multimode eight-arm sinuous antennas with different angles 2α are computed using FEKO and the results are shown in Table 13-10. As with other FI antennas, the quality of circular polarization decays with the increased mode number. Also, the antenna gain in general increases with the more pronounced interlacing between the arms. Modes 2 and 3 peak around 34° and 40° , respectively. Note that the lower-frequency end of operation is somewhat extended with the larger arm swings.

Most commercial sinuous antennas are four-arm structures and are designed to operate over different bands. The most common realization is a 5-cm diameter 2–18-GHz antenna operating in a dual-circular mode 1 or dual-linear mode. The dual-circularly polarized sinuous antenna has already been discussed. A linearly polarized version has similar properties to a planar log-periodic antenna. As with good log-periodic design having a typical growth rate of $\tau > 0.8$, there are several arc sections in the active region.

TABLE 13-10 Typical Characteristics at the Midband for an Eight-arm Sinuous Antenna with Various Swing Angles 2α

2α [°]	Mode ± 1			Mode ± 2				Mode ± 3

FIGURE 13-78 Measured return loss of a well-designed 5-cm cavity-backed sinuous antenna at the input and output of the beamformer

Opposite arms are fed antiphase ($0, 180^\circ$) and the two orthogonal arm-pairs of a four-arm sinuous antenna form two linearly polarized radiators. A small shift in the polarization vector with changing frequency is present as a consequence of the oscillating sinuous form of the structure. The polarization swings back and forth about the arms' central axis. When operating in circular polarization (with the addition of a 90° hybrid), this polarization oscillation or wobble does not degrade the polarization purity since each arm has identical rotation.

The return loss of a well-designed four-arm sinuous antenna is shown in Figure 13-78. Highly oscillatory behavior is due to the reflections inherent to the BFN, and after gating those out, a very smooth over 20-dB return loss is measured. The coupling between the two channels can be as high as -10 dB, while the losses in the BFN are typically below 1.5 dB at the highest end.

The performance of commercially available sinuous antennas, shown in Figures 13-79 and 13-80, clearly demonstrates high-quality wideband operation of these antennas.

Folded Spirals

A special case of sinuous antenna is the folded spiral, constructed as a spiral that is “folded” back on itself. The angular arm expansion of the folded spiral is the same as that of a sinuous antenna, and the main difference is in the shape or curvature of the arm bends. More specifically, the bends of a sinuous structure are rounded as opposed to the sharp tips of a folded spiral. The performance of the two antennas is similar, and often the folded spirals are referred to as sinuous antennas. Thus any reference to one can be equally applied to the other antenna.

Conical Structures

The unidirectional radiation from dual-polarized antennas follows the same rules and guidelines as shown for the conical spiral antenna (Section 13.2). Decreasing the cone angle results in a longer active region and will increase the forward radiation while suppressing the backward radiation (higher F/B ratio). Antenna parameters such as number of arms, radiation regions, modes, and so on, work the same as discussed in previous sections. The planar antenna geometry (spiral, sinuous, MAW, and so on) is projected on to a cone to form the conical antenna. As with conical spirals, the antenna phase center will move along the z -axis with frequency. Radiation will occur where the circumference is N guided wavelengths or the individual elements are resonant length. Sinuous and LP tooth geometries have similar radiation proportions for both polarizations (RCP and LCP). The MAW and inside-outside fed spirals have reduced directivities in the reflected (or outside fed) polarizations but might still be useful for certain applications.

Acknowledgments

The authors would like to thank Mr. Michael Buck and Mr. Neill Kefauver from the University of Colorado at Boulder, Mr. Nathan Stutzke from Ball Aerospace, and Mr. David DelRio from the University of Puerto Rico for their contributions to this chapter.

14.1 INTRODUCTION

Types of Horns and Applications

Electromagnetic horn antennas make a transition from waves propagating in a transmission line, usually a waveguide, and the launching of waves into another medium such as free-space or underground. They occur in a variety of shapes and sizes to fulfill many practical applications. These vary from communication systems, electromagnetic sensing, radio frequency heating, nondestructive testing and evaluation, biomedicine, and as a reference source for other antenna testing. Horns are used as feeds for other antennas such as reflectors, lenses, and compound antennas. Their widespread use stems from their simple, solid geometry and excellent performance when beam directivity is called upon. A summary of the many types of horns and typical applications with some references is given in Table 14-1. It is clear that one horn does not fit all situations—although their main purpose is to be a source of directive power or a directive receiver. For example, in communications and radio astronomy, a horn should be very low loss and be immune to extraneous signals including noise. Also, in some situations, it may be necessary that the horn operate over an octave or more of frequencies, such as in ultrawideband or pulse signal applications. Further, horns may be required to handle two orthogonal polarizations and minimize interference between them. These and other properties will be highlighted in this chapter. A collection of important historical papers dealing with horn antennas can be found in *Electromagnetic Horn Antennas*.¹

Some examples of these horns are pictured in Figure 14-1. Probably the most commonly occurring horn is the rectangular pyramidal family. The pyramidal horn shown

FIGURE 14-1 A selection of different types of horn antennas: (a) pyramidal horn; (b) profiled rectangular horn; (c) circular horn with axial corrugations and dual-probes for circular polarization; (d) conical corrugated horn; (e) dual-band coaxial horn with tracking; (f) compact profiled corrugated horn (Courtesy © CSIRO Australia 2007)

TABLE 14-1 Types of Horn Antennas and Their Applications

Classification	Application
<i>Rectangular</i>	
Smooth wall ¹⁻⁵	Standard gain, testing, sensing
Corrugated ⁶⁻¹⁰	Radar, heating
Dielectric-lined ¹¹⁻¹²	Radar, satellite
Profiled ^{1,13-15}	Satellite
Multimode ¹⁶⁻²⁰	Radar, satellite, radio astronomy, tracking
Self supporting ²¹⁻²³	Reflector feed
Ridged—double, quad ^{1,24-27}	Ultrawideband, radar, sensing
<i>Circular</i>	
Smooth-wall conical ^{1-2,28-33,110}	Feeds, testing, sensing
Corrugated ^{1,34-45}	Satellite, space, radio astronomy, tracking
Scalar ^{1,34,39-40,45}	Satellite, space, radio astronomy
Dielectric-lined ⁴⁵⁻⁵¹	Wideband, radio astronomy
Coaxial ^{55,52-58}	Multiband feed, probe, nondestructive testing, medical
Self supporting ⁵⁹⁻⁶⁴	Reflector feeds
Profiled ⁶⁵⁻⁷⁰	Satellite, radio astronomy
Special flange ^{39,71-73}	Feeds, medical
Longitudinal corrugation ⁷⁴⁻⁷⁶	Satellite, radio astronomy
Multimode ^{1,45,77-85}	Radar, satellite, radio astronomy
Ridged—double, quad ⁸⁶⁻⁸⁸	Ultrawideband, radar, sensing
<i>Other Types</i>	
Diagonal ^{1,89-90}	Radio astronomy, sensing
Elliptical—all types ⁹¹⁻⁹⁹	Reflector feed, radar, satellite
Superelliptical ¹⁰⁰	Feeds
Oblique aperture ¹⁰¹	Feeds
Dielectric—all types ¹⁰²⁻¹⁰⁸	Direct radiator

in Figure 14-1a is used as a primary gain standard since its gain may be calculated to within 0.1 dB by knowing its dimensions. Independent control of the beamwidths in the two principal planes is possible by varying the rectangular-aperture dimensions. A special case is sectoral horns, which are flared in only one plane. They radiate fan-shaped beams, broad in the plane orthogonal to the flare. Other rectangular horns (Figure 14-1b) can have a nonlinear profile to increase efficiency and lower sidelobes compared with a linear flare.

Circular geometries (for example, Figure 14-1c and d) are also in widespread use, with other shapes such as elliptical and superelliptical¹⁰⁰ providing additional variation when

required for beam-shaping. The conical horn is, by virtue of its axial symmetry, capable of handling any polarization of the exciting dominant TE_{11} mode. It is particularly well-suited for circular polarization. Despite its axial symmetry, however, the beamwidths in the principal planes are generally unequal. Like the pyramidal horn, the conical horn may be used as a primary standard since its gain is accurately calculable. Also, profiling will improve performance.

The dual-mode and corrugated (hybrid-mode) conical horns shown in Figure 14-1c, d, and f overcome the lack of axial symmetry in the radiation pattern, and at the same time, achieve diminution of cross-polarized radiation in the intercardinal planes to a very low level. In both cases, the aperture field of the horn is modified in such a way as to produce radiation patterns with axial symmetry. A horn with axial corrugations, shown in Figure 14-1c, converts part of the incident TE_{11} mode in circular waveguide into TE_{11} mode in short-circuited coaxial waveguide to generate sufficient TM_{11} mode in the horn to produce patterns with good axial symmetry. The coaxial horn in Figure 14-1e allows two frequency bands to be used simultaneously and also provides tracking in the highest band.

Horns can have metallic walls, be composed of dielectric material, or employ combinations. In this chapter, we concentrate on horns with metallic sidewalls, although in the last section we review briefly dielectric-only horns (see Table 14-1).

Important Characteristics of Horns

Performance determines the selection of a horn for a specific application. This selection is based on a number of quantities and qualities, usually

- Bandwidth properties
- Radiation pattern
- Gain and efficiency
- Phase center
- Polarization
- Input match
- Fabrication and cost

These attributes will be briefly considered in turn.

Bandwidth Properties The chosen application normally includes a range of frequencies. Horn antennas are often differentiated by their ability to cover a narrow or wide frequency range. This is sometimes expressed as a percentage bandwidth, which is

$$\% \text{ bandwidth} = 200 \frac{(f_{\max} - f_{\min})}{(f_{\max} + f_{\min})} \quad (14-1)$$

where f_{\min} and f_{\max} are the minimum and maximum operating frequencies. Another way to express the frequency properties is as a ratio such as f_{\max}/f_{\min} :1. For example, a corrugated horn could be designed to operate from 10 to 21 GHz. That is, the percentage bandwidth is about 71% or the frequency ratio is 2.1:1.

Radiation Pattern The radiated fields from a general antenna lie on the surface of an imaginary sphere enclosing it. In many applications, it is usual to assume the radius of this sphere is large and a far-field approximation can be employed (see Chapter 1).

This means in a spherical coordinate system, the radial components are negligibly small, and the remaining field components are in the θ - and ϕ -directions. In the far-field the electric \mathbf{E} and magnetic \mathbf{H} fields are related by the wave impedance of free-space η (≈ 376.7 ohms) as follows: $\mathbf{H} = (\hat{r} \times \mathbf{E})/\eta$. The radiated power density in the outward radial direction is, therefore,² $P_r = |\mathbf{E}|^2/2\eta$. The radiation pattern is the distribution of this power density over the far-field sphere. The general properties of antenna radiation patterns are described elsewhere. Particular to horns is that the power density is directed in front of the horn, often with specifications on the sidelobe and backlobe levels. Sections of the radiation pattern for horns are usually given as a function of the elevation variable θ at a constant azimuth angle ϕ . For linear polarization, the \mathbf{E} -, \mathbf{H} - and intercardinal (± 45 -degree) planes are the most useful constant ϕ -pattern cuts through the two-dimensional pattern. The main beam (usually the axial direction) can be described by the half-power beamwidth (HPBW) and the angle between a lower power level relative to the peak, say -10 or -12 dB down.

Gain and Efficiency Antenna gain is defined in another chapter of this handbook. Several different types of gain are used to describe horn antennas. The most commonly accepted definition of gain is provided by the IEEE (Std. 145 – 1993 §2.165), which is based on the power accepted by the antenna. This definition removes the power reflected from the input from the definition. Another definition, called *absolute gain*, is also used.² It retains the reflected power from the input, as this is an intrinsic property of the antenna. For horn antennas, there is often very little difference between these two definitions because the reflection coefficient is small. The absolute gain, G , differs from the IEEE definition by the factor $1/(1 - |\Gamma_{in}|^2)$, where Γ_{in} is the input reflection coefficient. Absolute gain will be used throughout this chapter.

For horn antennas, and aperture antennas in general, the aperture efficiency is another useful measure for comparing antennas. Aperture efficiency in the direction (θ_m, ϕ_m) is the ratio of the gain of the antenna in that direction and the gain of an ideal uniformly illuminated aperture given by

$$\eta_a = \frac{\lambda^2}{4\pi A} G(\theta_m, \phi_m) \quad (14-2)$$

where A is the total area of the aperture, λ is the wavelength at the operating frequency, and G is the gain function (Chapter 1). Many applications require the aperture efficiency on axis, i.e., $(\theta_m, \phi_m) = (0, 0)$.

Phase Center This is the apparent center of the spherical waves that emanate from the horn at a given radial distance (usually the far-field, although for feeds this will be the average distance to the reflector). At the phase centre and in the far-field region, the phase response of the radiation pattern in the vicinity of the main beam will be reasonably constant. The phase center can be calculated from the radiation pattern¹⁰⁹ or measured by adjusting the center of rotation until the measured phase of the pattern is constant across the main beam, say between the -12 dB points—or a wider range when the horn is used as a feed. The phase center can vary significantly with frequency when the pattern angles extend across the main beam. The phase center d_{pc} of a particular radiation pattern cut $\phi = \phi_i$, having a phase function $\Phi(\theta, \phi_i)$, can be calculated from

$$kd_{pc}(\phi_i) = \frac{C_{10}C_{01} - C_{11}C_{00}}{C_{01}^2 - C_{02}C_{00}} \quad (14-3)$$

where

$$C_{mn}(\phi_i) = \int_{\theta_1}^{\theta_2} \Phi(\theta, \phi_i)^m \cos^n \theta d\theta$$

$k = 2\pi/\lambda$ and $\theta = [\theta_1, \theta_2]$ is the angular extent of the pattern. Equation 14-3 was derived by a least-squares comparison of the horn phase function and the ideal phase over the specified angular range. Note that d_{pc} is given relative to the origin of the spherical coordinate system. It is easily seen that when the phase function has positive curvature relative to the origin, the phase center is in front of the horn, and when the curvature is negative, the phase center is inside the horn. The overall phase center of the horn can be estimated by averaging the phase centers of several pattern cuts.

Polarization The antenna radiation on the far-field sphere can be resolved into two components. The largest component in the direction of the desired polarization is called copolarization, and the orthogonal component is cross-polarization. Polarization performance measures of particular relevance to horns are peak cross-polarization for linear polarization and axial ratio for circular polarization (see Chapter 1). Measures of low cross-polarization are low peak levels in the intercardinal planes and even lower levels in the principal planes. There are several ways of measuring cross-polarization. For horns, the copolar pattern is obtained by aligning the test antenna on boresight with the polarization of the distant source antenna. The test antenna is then rotated about the phase center while maintaining this alignment. The signal that is measured is the copolar pattern. The cross-polar pattern is obtained by rotating the transmitter through 90° and repeating the radiation pattern measurement. The received signal is the cross-polar pattern. In this definition, the co- and cross-polarized field components, E_{cp} and E_{xp} , may be obtained from the spherical field components using

$$\begin{bmatrix} E_{cp} \\ E_{xp} \end{bmatrix} = \begin{bmatrix} \cos(\phi - \phi_o) & -\sin(\phi - \phi_o) \\ -\sin(\phi - \phi_o) & -\cos(\phi - \phi_o) \end{bmatrix} \begin{bmatrix} E_\theta \\ E_\phi \end{bmatrix} \quad (14-4)$$

where E_θ and E_ϕ are the spherical components in the θ - and ϕ -directions, ϕ is the azimuth angle, and ϕ_o is the reference polarization angle taken at the x-axis of the coordinate system. Axial ratio is the ratio of the major and minor axes of the polarization ellipse, usually on axis (or boresight) of the horn. If the polarization is perfectly circular, the axial ratio is 1. Axial ratio is usually expressed in dB.

Some horns have partially axisymmetric patterns, and this occurs when the far-field functions are $E_\theta(\theta, \phi) = F(\theta) \cos \phi$ and $E_\phi(\theta, \phi) = -G(\theta) \sin \phi$. In this case, $|F(\theta)|$ is the E -plane pattern function and $|G(\theta)|$ is the corresponding pattern in the H -plane. If $F = G$, the pattern is fully axisymmetric and, additionally, the cross-polarization is zero everywhere. Ideal corrugated horns have this property at the *balanced-hybrid condition* (see Section 14.4). Dominant mode circular horns have partially axisymmetric field functions. Horns with partial axisymmetry have zero cross-polarization in the E - and H -planes and peak cross-polarization in the intercardinal planes, the level given by the difference of the E - and H -plane pattern functions, and are $|F(\theta) - G(\theta)|/2$. The copolar pattern in the intercardinal planes is the average of the E - and H -plane pattern functions, $|F(\theta) + G(\theta)|/2$.

Input Match The input match is determined by two main reflection components: (1) reflection at the junction between the feeding waveguide and horn flare (i.e., the *throat*) and (2) reflection at the aperture due to transition from a guided wave to a radiating field.

The combination of these two components can produce a highly oscillatory return loss over the frequency band for some small horns, with a period approximately given by the distance between the junction and the aperture (i.e., period $\approx 720s/\lambda$ degrees where s is the distance between the throat and the aperture). Reflection from the transition to the flare is the most significant contributor for large aperture horns as the reflection at aperture diameters $> 2\lambda$ is usually small (> 20 dB). Most horns can be designed to have a return loss of 15 dB and higher. To achieve a good input match, considerable attention is paid to designing the input transition and the commencement of the horn flare.

Fabrication and Cost Horns are fabricated in many different ways from a variety of materials. The choice of fabrication method depends on cost and the intended application (weight, strength, heat, etc.). However, to achieve good efficiencies and performance, the inside metallic surfaces should be a good conductor (conductivity $\sigma > 1 \times 10^7$ S/m), unless the purpose is to intentionally load the horn. A lower conductor material is sometimes used for weight (e.g. carbon fiber) or mass-production (plastic or low-temperature metal with good casting properties) considerations, followed by a coating of high-conductor material (such as copper, gold, or silver) at least five skin-depths thick (i.e., $> 80 / \sqrt{f\sigma}$ mm, where f is the frequency in GHz). Additional passivation may be necessary to prevent corrosion or oxidation. Both material and labor costs are significant for this method of fabrication. In single applications, good performance can be obtained for moderate cost when horns are machined (on a lathe or machining center) from aluminum or jigged and brazed together from sheet-metal pieces, such as copper. Horns made from aluminum are dip-brazed while electroforming from copper is also possible. The material cost is negligible compared with labor costs in these approaches.

Effect of Horn Flare

Flaring a waveguide provides a directive radiation pattern and a smooth transition from the input to free-space. The field in the flare changes from a plane wavefront to a curved one, which is desirable for radiation. The surface across the face of the horn is called the *aperture*, and this surface is a convenient reference for calculating the radiated fields. The radiation characteristics of horns with aperture dimensions greater than about one wavelength may be calculated with reasonable accuracy by using equivalent currents (Huygens' principle) and an approximation to the aperture field. For single dominant-mode horns, the aperture field is approximated by the transverse electric field of that mode as it would exist in a uniform waveguide of the same cross-section and size as the horn mouth. In a waveguide that flares to a horn, it is clear that the boundary conditions require the existence of higher-order modes in addition to the fundamental mode. As a first approximation, it is usual to assume that the flare angle is small enough to permit the higher-mode field components to be neglected in comparison with those of the dominant mode.

Even when the flare angle is not particularly small, the above treatment gives useful design information if the effect of the curvature of the dominant-mode wavefront in the aperture is taken into account. In Figure 14-2, the field lines are shown as though the dominant mode were expanding as a cylindrical wave (in a sectoral horn) or a spherical wave (in a conical horn) with a radius of curvature at the aperture equal to L , the axial length of the horn in the section shown. The path difference between this curved wavefront and an ideal plane wave in the aperture constitutes a phase error that requires the planar fields of the dominant mode be modified by the inclusion of an approximate quadratic phase factor,

FIGURE 14-2 Phase error due to wavefront curvature in the horn aperture

$\exp(-jk\delta(x))$, where x is the normalized aperture coordinate and $k = 2\pi/\lambda$. In Figure 14-2, the distance from the wavefront to the aperture δ is

$$\delta(x) = \sqrt{L^2 + x^2} - L \approx \frac{x^2}{2L}; \quad 0 \leq |x| \leq \pm d/2 \quad (14-5)$$

Sometimes the slant length ℓ is employed instead of L in the quadratic phase factor. Throughout this chapter, the axial length L is used. At the aperture, the maximum excursion of the wavefront from planar is

$$\Delta = \frac{1}{2}d \tan \frac{\theta_f}{2} = 2\ell \sin^2 \frac{\theta_f}{2} \approx \frac{d^2}{8L} \quad (14-6)$$

where θ_f is the semi-flare angle of the taper. The approximation in Eq. 14-5 is reasonably accurate for $\theta_f < 35^\circ$; for larger angles the exact formula should be used.

The consequences of the quadratic phase factor are loss in gain accompanied by broadening of the radiation pattern, an increase in sidelobe levels, and filling in of the nulls. In the rest of this chapter, all pattern calculations are based on the above approximate model with quadratic-error correction applied as necessary.

Obliquity Factors

Radiation patterns of dominant (i.e. TE) mode horns are different in the principal planes because the transverse-field distribution and the associated field factor decays differently in the two orthogonal directions. The additional field decay is called an *obliquity*, or a *Huygens factor*, and is a pattern function multiplier that takes into account the effects of the mode propagation constant, mismatch at the horn aperture, and diffraction at the rim and surrounding surfaces.

On the θ -function in the far-field (E -plane for $\phi_o = 0$ in Eq. 14-4), the obliquity factor is represented by

$$F_\theta = \frac{1}{2} \left[1 + \frac{\beta}{k} \cos \theta + \Gamma \left(1 - \frac{\beta}{k} \cos \theta \right) \right] \quad (14-7)$$

while on the ϕ -function in the far-field (H -plane for $\phi_o = \pm 90$ degrees) the factor is

$$F_\phi = \frac{1}{2} \left[\cos \theta + \frac{\beta}{k} + \Gamma \left(\cos \theta - \frac{\beta}{k} \right) \right] \quad (14-8)$$

where β is the dominant mode propagation constant appropriate to the guide dimension at the horn mouth, Γ is the reflection coefficient presented by the aperture discontinuity and rim, while θ is the usual far-field polar angle. The first term corresponds to the incident mode and the second part its partial image scaled by Γ . In small-aperture horns, F_θ and F_ϕ are significantly different. For apertures larger than about two wavelengths, the aperture discontinuity is small, so that $\Gamma \rightarrow 0$, while $\beta/k \rightarrow 1$. Under these circumstances, F_θ and F_ϕ are nearly identical:

$$F_\theta \approx F_\phi \approx \frac{1}{2} (1 + \cos \theta) = \cos^2 \theta / 2 \quad (14-9)$$

When the horn aperture terminates in a metallic flange, the diffraction of the field at the aperture changes the obliquity factors to more general functions $F_\theta = f_1(\theta)$ and $F_\phi = f_2(\theta)$, where $f_1(\theta)$ and $f_2(\theta)$ depend on the geometry of the rim, the incident field, and the external currents. An extreme case is when the ground-plane is infinite, when $F_\theta = 1$ and $F_\phi = \cos \theta$. These obliquity factors will be used throughout this chapter for simplicity though recognizing that they can be replaced with Eq. 14-7 and Eq. 14-8 as the situation demands. Another extreme case is when the walls of the horn are infinitely thin. A closed-form solution for $f_1(\theta)$ and $f_2(\theta)$ is available for circular waveguides.¹¹⁰

Choice of Design Software

There are many excellent software packages available for analyzing horns and the choice can be bewildering. A wide variety of electromagnetic methods have been employed in these packages. Several methods and computer packages are referred to in this chapter and these are only a small sample of what is available to the antenna designer. However, every designer has their own special requirements. It is recommended, therefore, before investing a significant amount of time and money on a software package, consideration should be given to the most frequent design task. Choose aspects and trial problems to compare your application with each software package and assess their performance. These trial problems could be from a textbook or handbook such as this one. Evaluate the packages for accuracy, ease and speed of use, level of software support offered by the vendor, portability to other applications and to other computer platforms, and annual license fee. The effort expended in selecting a software package that best suits your needs will not go unrewarded in the long run.

14.2 RECTANGULAR HORNS

The first rectangular horns of the pyramidal variety were used by J. C. Bose in 1897, which he termed a "collecting funnel." However, horns were not studied in detail until forty years later.¹ Their forerunner was, of course, the hollow rectangular waveguide

analyzed (for the first time) only a few years before the horn. Since the waveguide represents a useful approximation for rectangular horns, we commence this section with a brief overview of rectangular waveguide results.

Radiation from Rectangular Waveguide

An open-ended rectangular waveguide operating in the dominant mode (TE_{10} or TE_{01}) has a useful broad radiation pattern. When the aperture terminates in an infinite ground-plane the radiated far-fields by the TE_{10} mode are given by

$$E_{\theta}(r, \theta, \phi) = \frac{2abE_o}{\pi} \frac{e^{-jkr}}{r} \cos \phi S\left(U \frac{b}{2}\right) C\left(V \frac{a}{2}\right) \quad (14-10a)$$

$$E_{\phi}(r, \theta, \phi) = -\frac{2abE_o}{\pi} \frac{e^{-jkr}}{r} \sin \phi S\left(U \frac{b}{2}\right) C\left(V \frac{a}{2}\right) \cos \theta \quad (14-10b)$$

where

$$U = \frac{1}{\lambda} \sin \theta \cos \phi,$$

$$V = \frac{1}{\lambda} \sin \theta \sin \phi,$$

$$S(x) = \frac{\sin x}{x} \quad \text{and} \quad C(x) = \frac{\cos x}{1 - \left(\frac{2x}{\pi}\right)^2}.$$

The waveguide width is a (the dimension in the H -plane) and the height is b (the dimension in the E -plane). E_o is a constant. Above cutoff of the TE_{10} mode, the maximum gain of this antenna is

$$G_{\max} = \frac{32}{\pi} \frac{ab}{\lambda^2} \frac{k}{\beta} \quad (14-11)$$

where $\beta = \sqrt{k^2 - (\pi/a)^2}$ is the propagation constant of the mode. Well above cutoff $\beta/k \rightarrow 1$, in which case the aperture efficiency is $8/\pi^2$ or about 81%.

Sectoral Horns

Sectoral horns are produced when the rectangular waveguide input is flared in either the E - or H -plane. The rectangular horn shown in Figure 14-3 is the result that occurs when the waveguide is flared in both planes. The radiation patterns of sectoral horns may be approximately computed^{2,16} as described in "Effect of Horn Flare." The results of such calculations in the planes of the flare are shown in Figures 14-4 and 14-5 for E - and H -plane flares, respectively. In each case, there is a family of curves corresponding to the normalized cylindrical-wave error $\Delta_{e,h}/\lambda$ due to the flare, where

$$\Delta_e = \frac{b}{2} \tan \frac{\theta_e}{2} \quad \text{and} \quad \Delta_h = \frac{a}{2} \tan \frac{\theta_h}{2} \quad (14-12)$$

$\theta_{e,h}$ is the half-flare angle in the E - and H -plane, respectively.

FIGURE 14-3 Geometry of rectangular horn: (a) overall perspective; (b) E -plane projection; (c) H -plane projection

For the same values of $\Delta_{e,h}/\lambda$, the phase error due to the flare has a much more pronounced effect in the E -plane than in the H -plane. The reason is simply that the field is constant across the aperture of a sectoral horn flared in the E -plane but varies sinusoidally (i.e. tapered) for one flared in the H -plane. The patterns also exhibit much higher minor-lobe levels for the former case.

The curves in both Figures 14-4 and 14-5 are reasonably accurate when either a or b is at least several wavelengths. For smaller apertures, it is necessary to multiply by the appropriate obliquity factor, F_θ or F_ϕ . The approximate form given by Eq. 14-9 is reasonably accurate for aperture dimensions greater than about 1.5λ .

FIGURE 14-4 Universal radiation patterns of horns flared in the E -plane (sectoral or pyramidal). The parameter is the normalized phase error Δ_e/λ .

FIGURE 14-5 Universal radiation patterns of horns flared in the H -plane (sectoral or pyramidal). The parameter is the normalized phase error Δ_h/λ .

The aperture field method is incapable of predicting the radiation pattern in the rear sector of a horn antenna without the wall currents and is not accurate in the wide-angle sidelobe region because it neglects diffraction at the aperture edges. The prediction of wide-angle and rearward-radiated fields is possible by using the techniques of the geometrical and physical theories of diffraction (GTD and PTD). It is impractical to attempt such a treatment here; the interested reader should consult the references.^{2,111-115}

Pyramidal Horns

The pyramidal horn of Figure 14-3 flares in both the E - and the H -planes. Its radiation patterns in these planes are the same as those of the corresponding flared sectoral horns, so they are limiting cases of the pyramidal horn. Thus, the E -plane patterns of a pyramidal horn are as shown in Figure 14-4, while its H -plane patterns are those shown in Figure 14-5. The horns are assumed to be fed from a rectangular waveguide with dimensions in the H - and E -planes of a_w and b_w , respectively. The axial lengths in these planes are

$$L_h = ha/(a - a_w) \quad \text{and} \quad L_e = hb/(b - b_w) \quad (14-13)$$

where h is the length of the flared section. For aperture dimensions greater than about 1λ , the patterns in the two planes may be controlled independently by adjusting the mouth dimensions.

The electric field in the far zone of the aperture of a pyramidal horn located in a ground-plane and containing the TE_{mn} mode is given by

$$(E_\theta(r, \theta, \phi))_{mn} = A_{mn} \frac{\sqrt{L_e L_h}}{4} \frac{e^{-jk_r r}}{r} e^{-j\pi(Ua + Vb)} \left[\cos \phi (F_+(U) + F_-(U))(G_+(V) - G_-(V)) \frac{n}{b} \right. \\ \left. + \sin \phi (F_+(U) - F_-(U))(G_+(V) + G_-(V)) \frac{m}{a} \right] \quad (14-14a)$$

$$(E_\phi(r, \theta, \phi))_{mn} = -A_{mn} \frac{\sqrt{L_e L_h}}{4} \frac{e^{-jkr}}{r} e^{-j\pi(Ua+Vb)} \cos\theta \left[\sin\phi (F_+(U) + F_-(U))(G_+(V) - G_-(V)) \frac{n}{b} \right. \\ \left. - \cos\phi (F_+(U) - F_-(U))(G_+(V) + G_-(V)) \frac{m}{a} \right] \quad (14-14b)$$

where

$$F_\pm(U) = e^{j\alpha_\pm(a+\alpha_\pm)\frac{k}{2L_h}} \left\{ K\left(\sqrt{\frac{k}{2L_h}}\left(\frac{a}{2} - \alpha_\pm\right)\right) + K\left(\sqrt{\frac{k}{2L_h}}\left(\frac{a}{2} + \alpha_\pm\right)\right) \right\} \\ G_\pm(V) = e^{j\beta_\pm(b+\beta_\pm)\frac{k}{2L_e}} \left\{ K\left(\sqrt{\frac{k}{2L_e}}\left(\frac{b}{2} - \beta_\pm\right)\right) + K\left(\sqrt{\frac{k}{2L_e}}\left(\frac{b}{2} + \beta_\pm\right)\right) \right\} \\ \alpha_\pm = \left(2U \pm \frac{m}{a}\right) \frac{\pi L_h}{k}, \beta_\pm = \left(2V \pm \frac{n}{b}\right) \frac{\pi L_e}{k}$$

$U = 1/\lambda \sin\theta \cos\phi$, $V = 1/\lambda \sin\theta \sin\phi$, L_e , and L_h are the axial lengths from the apex to the aperture in the E - and H -planes, while $K(z) = \int_0^z \exp(-j\xi^2) d\xi$ is the complex Fresnel integral, which can be integrated numerically or calculated approximately.¹¹⁶ The electric fields of the TM_{mn} modes are similar, and these are obtained by reversing the sign on the K -function in the parentheses (Eq. 14-14a) from $+$ to $-$ and similarly in Eq. 14-14b from $-$ to $+$. The E - or H -plane sectoral horns are special cases obtained by allowing L_h or $L_e \rightarrow \infty$ in Eq. 14-14, respectively. The distance of the phase center from the aperture normalized to the axial length in the E - and H -planes of pyramidal (and sectoral) horns, which was calculated using Eq. 14-3 and the phase of Eq. 14-14 for the main beam between the -12 dB points, are shown in Figure 14-6 as a function of $\Delta_{e,h}/\lambda$.

FIGURE 14-6 Phase center relative to the aperture in the planes of various horns as a function of the parameter Δ/λ , where Δ is the maximum deviation of the wavefront from planar in the designated plane. The minus sign indicates the phase center is located inside the horn.

The design of a pyramidal horn for specified beamwidths in the principal planes must be undertaken iteratively because of the need to fit the throat of the horn to a given input waveguide. A design procedure is outlined here:

1. Starting with the E -plane pattern, select a trial value for b to give an approximation to the desired half-beamwidth θ_{ebw} in degrees. Estimate b/λ from Figure 14-4 or use $b/\lambda \approx 44/\theta_{\text{ebw}}$. Select a value of horn length h , and calculate L_e from Eq. 14-13.
2. Compute the E -plane radiation pattern using Eq. 14-14. Refine b and h to create the desired beamwidth.
3. Repeat this procedure for the H -plane pattern. Choose an initial dimension a/λ from Figure 14-5 or use $a/\lambda \approx 40/(\theta_{\text{hbw}} - 15)$ where θ_{hbw} is the desired half-beamwidth in the H -plane in degrees. Calculate L_h from Eq. 14-13.
4. Compute and refine the H -plane radiation pattern using Eq. 14-14. Vary h , a , and b as needed to improve the design.
5. Once satisfied with this approximate design, refine further to achieve the desired performance (i.e., input match, polarization, etc.) by simulating the structure with accurate design software.

Gain

The maximum absolute gain of a rectangular horn radiating predominantly in the $\text{TE}_{10}/\text{TE}_{01}$ mode is

$$G_{\text{max}} = \frac{8}{\pi} \frac{a}{b} r^2 \left(|E_{\theta}(r, 0, 0)|^2 + |E_{\phi}(r, 0, 0)|^2 \right) \bigg|_{\substack{m=1, n=0 \\ m=0, n=1}} \quad (14-15)$$

where the electric field components E_{θ} and E_{ϕ} are given by Eq. 14-14 and $k \gg \pi/a$.

The gain of sectoral and pyramidal horns may be determined from Eq. 14-15 or from the normalized gain curves of Figures 14-7 and 14-8, provided the narrow dimension is at

FIGURE 14-7 Normalized gain of E -plane sectoral horn ($a \leq \lambda$)

FIGURE 14-8 Normalized gain of H -plane sectoral horn ($b \leq \lambda$)

least one wavelength. The parameters g_e and g_h are the gains of E - and H -plane sectoral horns ($g_{e,h}$ has no dimension). It is seen that the gain initially increases as the aperture dimension increases, and then reaches a maximum before decreasing. The decrease in gain is due to increasing cylindrical-wave phase error as the aperture increases while the length remains constant.

The points of maximum gain in each case occur approximately where the phase errors at the aperture in the E - and H -planes are respectively 90° and 135° . That is

$$k\Delta_e \approx \pi b^2 / (4\lambda L_e) = \frac{\pi}{2} \quad (14-16)$$

$$k\Delta_h \approx \pi a^2 / (4\lambda L_h) = \frac{3\pi}{4} \quad (14-17)$$

The gain of both sectoral and pyramidal horns¹¹⁷ may be expressed by

$$G = G_0 R_e R_h \quad (14-18)$$

where the gain G_0 relative to an isotropic radiator is given by

$$G_0 = 32ab / (\pi\lambda^2) \quad (14-19)$$

and $R_{e,h}$ is gain reduction factors equal to or less than unity, which account for the loss in gain due to phase error caused by the horn flare; thus $R_{e,h}$ is a function of $\Delta_{e,h}/\lambda$. Both factors can be computed from Eq. 14-15. They are shown graphically in Figure 14-9 and are listed in Table 14-2.¹¹⁸ For a sectoral horn, one of the axial lengths will be infinite, and the corresponding gain reduction factor $R_{e,h}$ will be 0 dB. An alternative way of calculating the gain of a pyramidal horn is to take the product of the gains of the corresponding sectoral horns, obtained from Figures 14-7 and 14-8, and then to multiply by the factor $\pi/32$.

FIGURE 14-9 Gain-reduction factor for *E*- and *H*-plane flares

In the previous discussion of gain, far-field conditions are implicitly understood. It may be shown,¹¹⁸ however, that Eqs. 14-15 and 14-18 may be used at a finite range (in the Fresnel zone) by a simple redefinition of terms. This is possible because the effect of finite range is to increase slightly the already existing quadratic phase error in the aperture due to the flare. Define new effective axial lengths as follows:

$$1/L'_e = 1/L_e + 1/r \quad \text{and} \quad 1/L'_h = 1/L_h + 1/r \quad (14-20)$$

where r is the distance from the aperture center to the field point. Then for all equations already defined for gain (Eqs. 14-15 to 14-19), G , R_e , and R_h are determined as before, but the effective lengths defined by Eq. 14-20 are used instead—even for sectoral horns where either L_e or $L_h \rightarrow \infty$.

When the a dimension (E -plane) in a sectoral or pyramidal horn is small $a \ll \lambda$, the close proximity of the magnetic walls causes errors in the gain equations (Eqs. 14-18 and 14-20). One can use the accurate expression (Eq. 14-15) or the approximation¹¹⁹:

$$G = R_e R_h \frac{4k^2 ab}{\pi^2 (1 + k/\beta)} \exp \left[\frac{ka}{2} \left(1 - \frac{\beta}{k} \right) \right] \quad (14-21)$$

in which R_e and R_h are as before except that in calculating R_e the parameter Δ_e must be slightly modified. Thus

$$\Delta_e = \beta b^2 / \left(8kL_e \cos^2 \frac{\theta_e}{2} \right) \quad (14-22)$$

where θ_e is the semi-flare angle in the E -plane and β is the phase shift of the dominant mode appropriate to the dimension a .

Equation 14-18, which may be called *Schelkunoff's gain formula*, includes the geometrical-optics field in the aperture of the horn and the effects of singly diffracted fields at the aperture edges. It does not, however, include effects due to multiple edge diffractions or diffracted fields that are reflected from interior horn walls. These effects manifest themselves in the form of small oscillations about the monotonic curve predicted by Schelkunoff's equations. The oscillations can be of the order of ± 0.5 dB for pyramidal horns with a gain of about 12 dB. They decrease to about ± 0.2 dB for horns with a gain of about 18 dB, and they appear to be less than ± 0.1 dB when the gain exceeds 23 dB.¹²⁰⁻¹²¹

Optimum-Gain Horns

A class of rectangular horns that historically has been used widely as a gain reference is the optimum-gain horn (sometimes called a "standard" gain horn). This is a pyramidal horn with dimensions such that maximum far-field gain is produced for given axial lengths in the E - and H -planes. From what has been said in connection with Eqs. 14-16 and 14-17, an optimum-gain horn will have aperture dimensions given approximately by

$$a = \sqrt{\alpha_1 L_h} \quad b = \sqrt{\beta_1 L_e} \quad (14-23)$$

where $\alpha_1 \approx 3\lambda$ and $\beta_1 \approx 2\lambda$. The effective gain of an optimum-gain horn is very close to 50% of its actual aperture area; its gain is

$$\text{Gain (dB)} = 8.1 + 10 \log_{10} (ab/\lambda^2) \quad (14-24)$$

Such a horn will have semi-half-power beamwidths (HPBW) given approximately by

$$\theta_{\text{ebw}} \approx 60 b \sin (0.45 \lambda / b) \text{ degrees,} \quad E\text{-plane}$$

$$\theta_{\text{hbw}} \approx 60 a \sin (0.63 \lambda / a) \text{ degrees,} \quad H\text{-plane}$$

and first-sidelobe levels of -9 dB and -16 dB, respectively. The H -plane sidelobe is not well defined, amounting to no more than a shoulder on the main beam.

In designing an optimum-gain horn, one generally knows the frequency, the desired gain G_d (initially given in dB, but converted to its value for the calculations), and the dimensions of the feed waveguide a_w and b_w .

1. The horn geometry needs to satisfy the following geometric constraint to be physically realizable (from Eq. 14-13, h is the same in both planes):

$$L_e \left(1 - \frac{b_w}{b} \right) = L_h \left(1 - \frac{a_w}{a} \right) \quad (14-25)$$

This equation results in a quartic polynomial for which the only solution of interest (real solution and $0 < a_w < a$) is

$$a = \sqrt{A_1 + A_2} - \frac{\left(b_w c_o - \frac{a_w^2}{8} \right)}{4A_1} + \frac{a_w}{4} \quad (14-26)$$

where

$$c_o = \frac{(G_d \lambda^2)}{g_1} \frac{\alpha_1}{\beta_1},$$

$$A_1 = \sqrt{A_2^2 + 3 \left(u + \frac{P}{u} \right)^2},$$

$$A_2 = \left(u - \frac{P}{u} \right) + \frac{a_w^2}{8},$$

$$u = \left| Q + \sqrt{Q^2 + P^3} \right|^{\frac{1}{3}},$$

$$P = \frac{c_o}{12} \left(\frac{(G_d \lambda^2)}{g_1} - \frac{a_w b_w}{4} \right), \quad \text{and} \quad Q = \frac{c_o^2}{128} \left(a_w^2 \frac{\beta_1}{\alpha_1} - b_w^2 \right).$$

For a pyramidal horn, $g_1 = 2\pi$, $\alpha_1 = 3\lambda$, and $\beta_1 = 2\lambda$.

2. Calculate the remaining horn parameters from $b = \frac{(G_d \lambda^2)}{g_1 a}$, $L_h = a^2 / \alpha_1$, $L_e = b^2 / \beta_1$, and $h = L_h (1 - a_w / a)$.
3. Refine the design with your most accurate software to take account of wall effects to obtain the desired gain and input match over the specified bandwidth.

A special case of Eq. 14-26 is when $Q = 0$. This gives $b_w = a_w \sqrt{\beta_1 / \alpha_1}$, so that $a = \lambda \sqrt{(G_d / g_1) (\alpha_1 / \beta_1)^{1/2}}$ and $b = \lambda \sqrt{(G_d / g_1) (\beta_1 / \alpha_1)^{1/2}}$, resulting in a simple dependence on desired gain and wavelength as in the case of conical horns (see Section 14.3).

Input Match

The input reflection coefficient of sectoral and pyramidal horns depends on the mismatch between the horn mouth and free-space, the length of the guide between the horn aperture and throat, and the mismatch at the junction between the uniform guide and the throat. Aperture mismatch can be significant in E -plane sectoral horns when b is large compared with the width a . The input return loss of an E -plane horn varies periodically as the horn length is varied, with minima occurring approximately every half-guide wavelength.^{16,122} The guide wavelength in the E -plane sectoral horn is equal to that in the feeding rectangular waveguide. The input reflection coefficient for an E -plane sectoral horn is approximately¹²³:

$$\Gamma_{in} \approx \Gamma_{je} + \Gamma_{ac} \exp(-2j\beta\ell_e) \quad (14-27)$$

where

$$\Gamma_{je} = \frac{1 - y_{je}}{1 + y_{je}} \quad (14-28)$$

is the reflection coefficient of the junction between the waveguide and the flare, $y_{je} = jH_0^{(2)}(k\rho_e)/H_0^{(2)}(k\rho_e)$, and ρ_e is the radius from the apex to the flare (see Figure 14-3b) and

$$\begin{aligned} \Gamma_{ac} = & -\exp\left(j2\Phi_e(k\rho_e) + ph\left\{H_0^{(1)}(k\rho_e)\right\}\right) \left(\frac{1}{4\theta_e\beta\ell_e} + \frac{1}{2\beta a} \left(\frac{\beta}{k} - 1\right)\right) \\ & \times \exp\left(\frac{1}{\beta} \sqrt{\frac{2k}{\pi a}} \exp\left(j\left(ka + \frac{\pi}{4}\right)\right)\right) \end{aligned} \quad (14-29)$$

is the aperture reflection coefficient, where $\Phi_e(x) = a \tan\left(\frac{\text{Re}\{Z_e(x)\}}{1 + \text{Im}\{Z_e(x)\}}\right)$, $Z_e(x) = \frac{H_0^{(1)}(x)}{H_1^{(1)}(x)}$, and θ_e is the semi-flare angle in the E -plane (see Figure 14-3b). In Eqs. 14-28 and 14-29, $H_n^{(1)}(x)$ and $H_n^{(2)}(x)$ are the Hankel functions of types 1 and 2 of order n . An example of the use of Eq. 14-27 is shown in Figure 14-10 for an E -plane sectoral horn with $a = 7.214$ cm, $b = 3.404$ cm, $\ell_e = 42.15$ cm, and $\theta_e = 16.5^\circ$. The approximate expression in Eq. 14-27 is in reasonable agreement with measured results.¹²³

In all dominant-mode rectangular horns, the reflection coefficient due to the aperture Γ_{ap} of the TE_{10} mode at the aperture is given approximately by

$$\Gamma_{ap} \approx \left(\frac{1 - y_{11}}{1 + y_{11}}\right) \quad (14-30)$$

where the aperture admittance y_{11} of this mode when input on an infinite flange¹²² is given by

$$\begin{aligned} y_{11} = & \frac{2jk^2}{\pi ab\beta} \left(\int_0^{\alpha_o} d\alpha \int_0^{a \sec \alpha} dx + \int_{\alpha_o}^{\pi/2} d\alpha \int_0^{b \cos \alpha} dx \right) \exp(-jkx)(b - x \sin \alpha) \\ & \times \left(\frac{1}{k_c} \left(1 + \left(\frac{k_c}{k} \right)^2 \right) \sin(k_c x \cos \alpha) + \left(1 - \left(\frac{k_c}{k} \right)^2 \right) (a - x \cos \alpha) \cos(k_c x \cos \alpha) \right) \end{aligned} \quad (14-31)$$

where $k_c = \pi/a$ and $\alpha_o = a \tan(b/a)$. The return loss for the aperture is typically better than 25 dB for $a > 2\lambda$ and $a < b < 2a$.

The mismatch of an H -plane sectoral horn differs somewhat from that of the E -plane horn, in that the mismatch at the junction of the horn and rectangular waveguide is much

FIGURE 14-10 Reflection coefficient of E -plane sectoral horn ($a = 7.214$ cm, $b = 3.404$ cm, $\ell_e = 42.15$ cm, $\theta_e = 16.5^\circ$). The experimental data are from Jull.¹²³

smaller than that at the horn aperture. The corresponding equation to Eq. 14-28 for H -plane junctions is not very accurate, and it has been found that a good estimate of the mismatch can be obtained from aperture reflection only. Thus, for the H -plane sectoral horn $\Gamma_{in} \approx \Gamma_{ap} \exp(-2j\beta h)$, where Γ_{ap} is given by Eq. 14-31. The result is that the input match to an H -plane sectoral horn is almost constant in magnitude (for a constant aperture width a) and varies only in phase as the length of the horn is changed.¹⁶

A broadband match is best obtained in the E -plane sectoral horn by treating the two discontinuities separately. The mismatch at the junction of the waveguide and horn may be eliminated with a reactive window (usually inductive) at the junction. The horn aperture is frequently matched to free-space by using a radome of appropriate thickness and dielectric constant. If no radome is used, a match may be obtained by using small reactive discontinuities at the aperture.

The problem of obtaining a broadband match with the H -plane horn is somewhat easier because of the small discontinuity at the horn throat. Generally, only the aperture needs to be matched, and the techniques mentioned for the E -plane horn may be employed.

An estimate of the input reflection coefficient in a pyramidal horn can be found from

$$\Gamma_{in} \approx \Gamma_{je} + \Gamma_{ap} \exp(-2j\beta h). \quad (14-32)$$

where Γ_{je} is given by Eq. 14-28 and Γ_{ap} by Eq. 14-30. Results from Eq. 14-32 and mode matching (MM) software with an infinite flange are shown in Figure 14-11 along with experimental results for a 20 dB optimum-gain horn ($a = 100$ mm, $b = 74$ mm, $h = 217$ mm, WR-75 input) supplied by Flann Microwave (model 1724-20) (shown in Figure 14.1a). Also shown are results for this horn from the commercial software package CST Microwave Studio.¹²⁴ Differences between the accurate theory and experiment can be attributed to conditions at the aperture (i.e., thin or large flange) and the junction between the waveguide and the flare. Generally, horns having a gain of 20 dB or more and moderate flare angles, such as optimum horns, usually are well matched to a rectangular waveguide supporting

FIGURE 14-11 Reflection coefficient of Ku-band 20 dB optimum-gain horn with WR-75 input waveguide and $a = 100$ mm, $b = 74$ mm, and $h = 217$ mm

only the dominant mode. Where the overall match has to be improved, techniques similar to those described for sectoral horns may be adopted. However, when there are issues with matching, after an initial design matching section, steps in cross-section or irises can be introduced and assessed with accurate design software.

Other Rectangular Horns

There are a wide variety of other smooth-walled horns with a rectangular cross-section in general use. The most important ones are covered in this section.

Diagonal Horns The simplest example of a dual-mode horn⁸⁹ in which two spatially orthogonal dominant modes, the TE_{10} and the TE_{01} , are excited with equal amplitude and phase in a square waveguide that flares to a pyramidal horn. In this case, the electric field in the aperture is aligned with one of the diagonals. A simple transformation from rectangular guide to diagonal horn is shown in Figure 14-12. Another method of excitation is the use of coaxial-fed orthogonal probe couplers in square waveguides along with a suitable power splitter.

For apertures in which $d > 2\lambda$ the E -, H -, and intercardinal-plane patterns will be essentially identical to well below the 10-dB level, as is evident in the patterns shown in

FIGURE 14-12 Transition from rectangular waveguide to diagonal horn

FIGURE 14-13 Principal- and intercardinal-plane patterns of narrow-flare angle diagonal horn ($d > 2\lambda$): —, E - and H -planes; ····, intercardinal copolar; and - - -, intercardinal, cross-polar

Figure 14-13 for narrow flare-angle ($< 10^\circ$). True axial symmetry is not achieved, however, because the intercardinal-plane patterns differ markedly in sidelobe structure from those in the principal planes. Moreover, a significant amount of cross-polarization is manifested in the intercardinal planes, as shown by the dashed curve in Figure 14-13.

By writing $u = \pi d \sin \theta / \lambda$, the principal patterns of the diagonal horn are given by

$$E_{e,h} = \pm F_{\theta,\phi} S(u/\sqrt{2}) \cdot C(u/\sqrt{2}) \quad (14-33)$$

and the cross-polarization is zero, while in the intercardinal planes

$$E_{cp,sp} = \frac{1}{2} (F_\theta \cdot S(u) \pm F_\phi \cdot C(u)) \quad (14-34)$$

where F_θ and F_ϕ are the obliquity factors discussed in the section, “Obliquity Factors,” earlier in the chapter, and the functions S and C are defined below Eq. 14-10. When $d > 2\lambda$, it was observed that $F_{\theta,\phi} \rightarrow 1$; this is the case for the patterns shown in Figure 14-13. Important characteristics of large-aperture diagonal horns are summarized in Table 14-3. Improved design accuracy for the radiation from medium flare angle ($< 35^\circ$) horns is obtained with Eq. 14-14 by combining equal amplitude TE_{10} ($m = 1, n = 0$) and TE_{01} ($m = 0, n = 1$) modes.

Prime-focus feed horns have small apertures ($d \sim \lambda$) for frequently used f/D ratios. The diagonal horn is at a disadvantage here because the disparity between the obliquity factors destroys the circular symmetry of the beam. It has been observed in practice, however, that in the neighborhood of $d = 1.23\lambda$, a diagonal horn possesses axial-beam symmetry with full widths of 40 and 73° at the -3 - and -10 -dB levels. Apparently, in this case, the

TABLE 14-3 Characteristics of Diagonal Horns⁸⁹

Parameter	Principal Planes	45° and 135° Planes
3-dB beamwidth, °	58.5 λ/d	58 λ/d
10-dB beamwidth, °	101 λ/d	98 λ/d
Angular position, first null, °	81 λ/d	70 λ/d
Angular position, first lobe, °	96 λ/d	92 λ/d
Level of first sidelobe	-31.5 dB	-19 dB
Angular position, second null, °	122 λ/d	122 λ/d
Angular position, second lobe, °	139 λ/d	147 λ/d
Level of second sidelobe	-41.5 dB	-24 dB

values of Γ and β/k (see “Obliquity Factors”) happen to be such that the obliquity factors are approximately equal.

Multimode, Stepped, and Profiled Rectangular Horns Multimoding in horns refers to the presence of more than one mode in the aperture at an intentionally significant level. Usually these modes are in addition to the dominant mode. There are essentially two main reasons for multimoding. One reason is to achieve the highest possible aperture efficiency for a given aperture size and the other is to lower the sidelobes in the E -plane to be similar to those in the H -plane. Both approaches will now be described.

The main method to date to design high-efficiency rectangular horns is based on achieving a uniform aperture distribution with unidirectional polarization. Horns designed this way employ TE_{0n} or TE_{n0} ($n = 1, 3, \dots$) modes with approximate amplitudes of $1/n$.^{16,20,14} Aperture efficiencies in excess of 90% can be achieved using this approach, compared with a maximum of about 81% with conventional rectangular horns. Steps are introduced along the length of the horn to excite the desired amplitude and a length of horn is used to bring the modes into phase equality. The bandwidth of operation at the highest efficiency is usually about 10%. However, the length of both conventional and dual-mode horns is relatively long due to the linear taper from the waveguide input to the waveguide step that is used to excite the TE_{0n}/TE_{n0} modes. Another way of achieving high aperture efficiency is to design a mode converter in the horn by stepping or profiling the cross-section in the flare to the aperture in order to excite modes of the desired amplitude and phase. It has been shown¹⁴ that the highest efficiency can be obtained by designing a mode converter that excites predominantly TE modes. However, when the horn is relatively small, there is significant reflection at the aperture. It has been shown that horns of width given approximately by

$$\frac{a}{\lambda} \approx \frac{n}{2} + \frac{(15+n)}{160} \quad (14-35)$$

where n is an odd integer (<9), the aperture efficiency is close to maximum, and ~100% over a modest bandwidth. Bird and Granet¹⁵ describe a way of achieving high efficiency by optimizing both profiles of the horns. An example of this type of horn is shown in Figure 14-1b.

Flare-angle changes may also be used in a pyramidal horn to generate the hybrid TE_{12}/TM_{12} pair, as shown by Cohn¹³ and illustrated in Figure 14-14. It is assumed that only the dominant mode propagates at the throat. Conversion to TE_{12}/TM_{12} modes

FIGURE 14-14 Section through rectangular horn with flare-angle change

occurs at the point where the flare-angle changes from θ_f to 0. Relative to unity for the TE_{10} mode, the TE_{12}/TM_{12} amplitude is

$$A \approx j2\theta_f d / 3\lambda_g \quad (14-36)$$

providing θ_f is small (i.e., $< 23^\circ$), and where λ_g is the TE_{10} -guide wavelength corresponding to the waveguide dimension d . It is seen that the hybrid-mode phase leads that of the dominant mode by 90° . Therefore, the constant-diameter section ℓ must create a 270° differential shift to obtain correct phasing in the aperture. The length ℓ can be calculated from

$$\ell(\beta_{10} - \beta_{12}) = 3\pi/2 \quad (14-37)$$

where $\beta_{10} = k\sqrt{1 - (\lambda/2d)^2}$ and $\beta_{12} = k\sqrt{1 - (\lambda/2d)^2(4 + (d/w)^2)}$ where w is the other waveguide dimension (into the page of Figure 14-14). If no phasing section is used (i.e., $\ell = 0$), mode conversion still occurs and Eq. 14-36 applies as before. This means that the TE_{12} and TM_{12} energy is improperly phased relative to the TE_{10} and performance is that of a simple flared horn with spherical-wave error in the aperture. This complication must be included in any design.

Beam-shaping with a square aperture pyramidal horn can be accomplished by combining the dominant TE_{10} mode with a hybrid mixture of higher-order TE_{12} and TM_{12} modes, as shown by Jensen^{1,17} (Figure 14-15). These two higher-order modes, which have the same propagation constant, can exist as a hybrid pair, and their relative amplitudes can be adjusted to give a purely linearly polarized aperture field. When added in the proper phase to the TE_{10} field in the aperture, the resulting distribution is tapered in the E - as well as in the H -plane. If one assumes that dual-polarization capability is required, the input waveguide in Figure 14-15 will be square with a side of dimension d_1 such that the TE_{12}/TM_{12} pair cannot propagate; i.e., $d_1 < \sqrt{5}\lambda/2$. At the mode-generating step, both dimensions of the guide increase to d_2 , where $d_2 > \sqrt{5}\lambda/2$. The ratio d_2/d_1 is in the range 1.2 to 1.3, which means that d_1 is large enough to support 11, 02, and 20 index modes as well as the dominant TE_{10} (or TE_{01}). For this reason, a tapered transition is needed to transform from purely dominant-mode guide (for which $\lambda < 2d_0 < \sqrt{2}\lambda$) to the input guide of side d_1 . A constant-dimension phasing section of length ℓ (see Figure 14-14) is used to ensure correct phasing at the aperture. Unfortunately, the operation is relatively narrowband; 3 to 4% is typical.

FIGURE 14-15 Dual-mode pyramidal horn

If the aperture is large enough to make the obliquity factors essentially unity ($d > 2\lambda$) and the semi-flare angle is small enough to render the spherical-wave error negligible, the patterns of a multimode horn are given by

$$\left. \begin{array}{ll} E\text{-plane} & E = S(u) \left(1 + \alpha\sqrt{2} \frac{u^2}{\pi^2 - u^2} \right) \\ H\text{-plane} & E = C(u) \end{array} \right\} \quad (14-38)$$

where S and C are defined beneath Eq. 14-10, $u = \pi d \sin \theta / \lambda$, and α represents the fractional TE_{12}/TM_{12} -mode content relative to unity for the TE_{10} mode. The interesting range for α is between 0.42 and 0.55, corresponding to a power level in the TE_{12}/TM_{12} mode between 7.5 and 5 dB below that in the dominant mode. The patterns shown in Figure 14-16 were calculated from Eq. 14-38 for $\alpha = 0.464$. Note that the main-beam shapes are nearly identical in the two planes down to the -20 -dB level, while the first E -plane sidelobe level is very low, approximately -45 dB. The cross-polar level in the 45° -plane is < -30 dB across most of the main beam. The full HPBW in all planes is $69\lambda/d$ degrees.

To design a horn using flare angle changes to give the patterns of Figure 14-16, it is required that $|A| = \alpha\sqrt{2}$ with $\alpha = 0.464$. Thus the condition is $2\theta_f d / 3\lambda_g = 0.656$. This gives $\theta_f = 56\lambda_g/d$ degrees. For a small-aperture horn (e.g., $d < 2\lambda$), this condition leads to a relatively large value for θ_f , which may violate the small-angle condition used in deriving Eq. 14-36. In this case, two or more separate flare changes may be used, since the A coefficients are additive, although frequency sensitivity will increase. Good pattern performance over a 30% bandwidth has been reported for the single-flare-change case.

Dielectric-lined Rectangular Horns Dielectric can be placed on the walls of a rectangular horn to increase the gain or aperture efficiency instead of multimoding (see Figure 14-17).¹¹⁻¹² The dielectric loading provides an extra degree of freedom in design, and in shaped-beam applications from satellites, a smaller number of elements can be used as the aperture efficiency is higher than conventional rectangular horns. The disadvantages are that horns

FIGURE 14-16 Calculated power patterns of a multimode pyramidal horn for $\alpha = 0.464$

FIGURE 14-17 Geometry of dielectric-loaded rectangular horn with a flange

are heavier, have higher loss, are more difficult to fabricate (e.g., the dielectric must be fixed in close contact with the E -plane walls), and in space applications the material may outgas. The aim is to make the E - and H -plane sidelobes similar, and this is done by increasing the H -plane sidelobes. When a dielectric of thickness t is used, where

$$t \approx \frac{\lambda}{4\sqrt{\epsilon_{r1} - \epsilon_{r2}}} \quad (14-39)$$

and ϵ_{r1} and ϵ_{r2} are the dielectric constants in regions 1 and 2 shown in Figure 14-17, the field in the H -plane is also almost uniform. This improves the illumination efficiency of small and large aperture horns and is not limited by aperture size as in multimode horns.

The radiation fields can be obtained in a manner similar to that for the rectangular horn by assuming a quadratic phase factor on the dominant mode of a dielectric-loaded waveguide, the LSE_{10} mode. The result is an extension of Eq. 14-14 (with $m = 1$ and $n = 0$), in other words,

$$E_{\theta}(r, \theta, \phi) = A_{10} \frac{jk}{2\pi} \frac{e^{-jkr}}{r} N_x \cos \phi \quad (14-40a)$$

$$E_{\phi}(r, \theta, \phi) = -A_{10} \frac{jk}{2\pi} \frac{e^{-jkr}}{r} \cos \theta N_x \sin \phi \quad (14-40b)$$

where

$$N_x = \frac{\sqrt{L_e L_h}}{2\beta} e^{-j\pi Vb} [G_+(V) + G_-(V)] [F_{2+}(U) + F_{2+}(-U) + F_{2-}(U) + F_{2-}(-U) - j c_o (e^{j\pi Ua} (F_{1+}(-U) - F_{1+}(-U)) + e^{-j\pi Ua} (F_{1+}(U) - F_{1+}(U)))] \quad (14-41)$$

and where

$$F_{i\pm}(U) = e^{j\frac{\beta}{2L_h}\alpha_{i\pm}[a(2-i)+\alpha_{i\pm}]} \left\{ K\left(\sqrt{\frac{\beta}{2L_h}}(w-\alpha_{i\pm})\right) + K\left(\sqrt{\frac{\beta}{2L_h}}\left(\frac{a}{2}+\alpha_{i\pm}\right)\right) \right\}$$

and $G_{\pm}(V)$, $K(\cdot)$, U , and V are defined with Eq. 14-14, $\alpha_{i\pm} = (2\pi U \pm k_i) \frac{L_h}{\beta}$, $c_o = \frac{\cosh(k_2 w)}{\sin(k_1 d)}$, $k_i = \sqrt{k^2 \epsilon_{ri} - \beta^2}$, and β is the propagation constant of the LSE₁₀ mode that is obtained by solving $k_2 \tan k_2 w = k_1 \cot k_1 d$. An approximate lower bound for β is

$$\frac{\beta}{k} \approx \sqrt{1 + (\epsilon_{r1} - 1) \left(\frac{2d}{a} - \frac{1}{\pi} \sin\left(\frac{2\pi d}{a}\right) \right) - \left(\frac{\pi}{a} \right)^2 + (\epsilon_{r2} - 1) \frac{2w}{a} \left(1 - \frac{1}{\pi} \sin\left(\frac{2\pi w}{a}\right) \right)} \quad (14-42)$$

which can be used as an initial value in finding accurately the roots of the transcendental equation. Note that the argument of the Fresnel integral $K(z)$ in region 1 ($F_{1\pm}$) is complex since k_1 is imaginary for high-efficiency horns. Padé approximations to these integrals are available.¹¹⁶ Computed and measured radiation patterns in the H -plane of a dielectric-loaded horn are shown in Figure 14-18 at 12.5 GHz. The dimensions of the horn in the aperture are $a = 61$ mm, $b = 52.8$ mm, $d = t = 4.1$ mm, $\epsilon_{r1} = 3.07$, $\epsilon_{r2} = 1$, $h = 228.6$ mm, and it was fed from a WR75 waveguide. The theoretical values were obtained from Eq. 14-40. The sidelobe levels in the H -plane are about -16 dB down, and this compares with about -13.5 dB (measured) for the E -plane. However, the main beam is very similar.

The absolute gain of the dielectric-loaded horn is given by

$$G_{\max} = \frac{2\pi}{P_{\text{in}}} r^2 (|E_{\theta}(r, 0, 0)|^2 + |E_{\phi}(r, 0, 0)|^2) \quad (14-43)$$

where $P_{\text{in}} = \sqrt{\frac{\beta}{k}} \frac{b}{2} [w(1 + S(2k_2 w) + d |c_o|^2 (1 - S(2k_1 d))]$, S is defined below Eq. 14-10, and the fields are given by Eq. 14-40. The aperture efficiency of a dielectric-loaded horn can exceed that of the unloaded horn providing $a > \lambda$. Absolute gain results are

FIGURE 14-18 Measured and computed radiation patterns of a dielectric-loaded rectangular horn at 12.5 GHz with aperture geometry $a = 61$ mm, $b = 52.8$ mm, $d = 4.1$ mm, $\epsilon_{r1} = 3.07$, and $\epsilon_{r2} = 1$ (solid line — theory, dashed line --- experiment)

TABLE 14-4 Measured and Computed Gain of Dielectric-loaded Rectangular Horn with Aperture Geometry $a = 61$ mm, $b = 52.8$ mm, $d = 4.1$ mm, $\epsilon_{r1} = 3.07$, and $\epsilon_{r2} = 1$

Horn Type	12.25 GHz		12.5 GHz		12.75 GHz	
	Exp. dBi	Theory dBi	Exp. dBi	Theory dBi	Exp. dBi	Theory dBi
Unloaded	17.34	17.48	17.69	17.65	17.75	17.80
Dielectric-loaded	17.89	18.05	18.12	18.25	18.30	18.42

(experimental uncertainty ± 0.14 dB)

summarized in Table 14-4 for loaded and unloaded horns. The measured aperture efficiency in the loaded case is in excess of 91% across the band. The mismatch in a horn due to the dielectric loading is relatively small ($\epsilon_{r2} = 1$), although the bandwidth decreases and the aperture reflection increases as ϵ_{r1} is increased. However, for $\epsilon_{r1} < 4$ the effect is relatively small on the return loss. To obtain best results the dielectric loading was flared from the throat region to the aperture. Reduced efficiencies and lower sidelobes in both planes result when the dielectric loading on the wall of the transition is made too short.

14.3 CIRCULAR HORNS

Radiation from hollow circular pipes was investigated initially in the late 19th century by O. Lodge and J. C. Bose, and this was followed by theoretical work on circular waveguides by Lord Rayleigh.¹ However, it was not until the 1930s and 1940s that the first detailed studies of conical horns were undertaken, mainly by Southworth and King,^{1,28-29} the basis of current day design methodology. Because the circular waveguide is a cornerstone to this methodology, we summarize its radiation properties.

Radiation from Circular Waveguide

The radiation mechanism for a circular waveguide is identical to that for radiation from a rectangular waveguide, except that there is a different infinite set of TE and TM modes. The dominant mode of a circular waveguide is the TE_{11} mode, which has different polarization properties than the dominant mode of a rectangular waveguide—due mainly to the fact that the boundary conditions on the circular pipe cause the field lines to curve instead of be unidirectional. The radiated far-fields of the TE_{11} mode are given by

$$E_{\theta}(r, \theta, \phi) = 2\pi a \frac{e^{-jkr}}{r} J_1(k_c a) \frac{J_1(wa)}{k_c wa} \cos \phi \quad (14-44a)$$

$$E_{\phi}(r, \theta, \phi) = 2\pi a \frac{e^{-jkr}}{r} J_1(k_c a) \frac{k_c J_1'(wa)}{k_c^2 - w^2} \cos \theta \sin \phi \quad (14-44b)$$

where a is the aperture radius, $w = k \sin \theta$, and $k_c a = 1.841181$. The function J_n is the Bessel function of order n .¹²⁵ A prime on this function indicates the first derivative with respect to the argument. A more general form of Eq. 14-44 is available for circular waveguides with infinitely thin walls.¹¹⁰ This exact solution due to Weinstein¹¹⁰ finds wide application for feeds and measurement probes. The maximum gain of a circular waveguide operating in the TE_{11} mode only is

$$G_{\max} = 0.209(ka)^2 \frac{k}{\beta} \left(1 + \frac{\beta}{k}\right)^2 \quad (14-45)$$

where $\beta = \sqrt{k^2 - k_c^2}$ is the propagation constant. At frequencies well above cutoff ($\beta \approx k$), the input reflection coefficient Γ_{in} is small and $G_{\max} \approx 0.837 (ka)^2$, giving an aperture efficiency of 83.7%. Choke rings can be used either inside the horn or at the aperture to tailor the radiation pattern of small horns to minimize cross-polarization over a moderate bandwidth.¹⁶ The E -plane beamwidth is wider than the H -plane up to a particular ka value. A choke ring placed concentric with the aperture with depth 0.2 to 0.26 λ can reduce the E -plane beamwidth to almost the same as the H -plane beamwidth.⁷¹ This method becomes less effective for larger diameter conical horns as the radiated field becomes too small to excite the ring slot. As a consequence, recourse must be made to other methods for achieving axisymmetric patterns. Some of these methods are described in the following sections.

Conical Horns

The conical horn excited by a circular waveguide in the TE_{11} mode is the counterpart of a pyramidal horn with TE_{10} excitation in a rectangular guide, and in many respects, its behavior is quite similar. The modes in an infinite conical horn are exactly expressible in terms of a combination of spherical Hankel and Legendre functions. Numerical methods such as mode matching, finite elements, or finite-difference time domain are usually preferred because accurate design information can be obtained for conical horns. Nevertheless, considerable physical insight is possible from a dominant mode approximation that parallels the rectangular horn description.

The geometry of the conical horn is given in Figure 14-19. Assuming the usual quadratic phase approximation, the fields radiated by this horn operating in the dominant mode is

$$E_\theta(r, \theta, \phi) = \frac{jE_o ka^2}{2} \frac{e^{-jkr}}{r} (G_0(w) - G_2(w)) \cos \phi \quad (14-46a)$$

$$E_\phi(r, \theta, \phi) = -\frac{jE_o ka^2}{2} \frac{e^{-jkr}}{r} \cos \theta (G_0(w) + G_2(w)) \sin \phi \quad (14-46b)$$

where $G_m(w) = 1/a^2 \int_0^a J_m(p_{11} \rho'/a) J_m(w\rho') \exp(-jk\rho'^2/2L) \rho' d\rho'$, $p_{11} = 1.841184$, and $w = k \sin \theta$. The above equations, obtained by Narasimhan and Rao,³¹ give useful results for semicone angles less than about 35° for medium-to-long horns ($L > 5\lambda$). For wider flare angles, the argument of the first Bessel function should be $(p_{11}/\theta_o a \tan(\rho'/L))$.

FIGURE 14-19 Geometry of conical horn

FIGURE 14-20 The universal radiation patterns of a conical horn in the (a) E -plane and (b) H -plane. The parameter is the normalized phase error Δ/λ .

The appropriate obliquity factors must be applied to Eq. 14-46 to suit the conditions at the aperture. The functions G_m are best evaluated by numerical integration, although a series solution is possible in terms of Lommel functions. As with the pyramidal horn, the radiation pattern of the conical horn is strongly dependent on the flare geometry. The E - and H -plane patterns are plotted in Figure 14-20 as a function of $\Delta = a^2/2L$, the distance in wavelengths between the spherical wavefront and the aperture. The quadratic phase increases as the semi-angle is increased, causing the patterns to broaden and the sidelobes to fill in. Figure 14-21 shows computed results and measured data from

FIGURE 14-21 Principal plane patterns of a conical horn with $a = 1.7\lambda$, $L = 3.5\lambda$, and $\theta_0 = 25.91^\circ$: solid curve, E -plane; broken curve, H -plane; no marker, Eq. 14-46; open diamond, CST Microwave Studio; solid triangle, E -plane experiment (after King²⁹ © IEEE 1950); solid diamond, H -plane experiment (after King²⁹ © IEEE 1950).

FIGURE 14-22 Calculated gain of a conical horn as a function of aperture diameter with axial length as parameter (after King²⁹ © IEEE 1950)

King for a horn with $a = 1.7\lambda$ and $L = 3.5\lambda$. Two sets of computed results are plotted: those given by Eq. 14-46 and predictions by CST Microwave Studio,¹²⁴ an accurate computer package. There is good agreement in the E -plane, although there is surprising discrepancy with King's measurements²⁹ in the H -plane. The computed return loss from Microwave Studio is >25 dB. The phase center in the E - and H -planes (given by Eq. 14-3) and the phase of Eq. 14-46 are plotted in Figure 14-22 as a function of Δ/λ between the -12 dB points of the main beam.

The absolute gain of a dominant-mode conical horn is

$$G_{\max} = \frac{4}{\beta/k} \frac{(ka)^2 |G_0(0)|^2}{J_1^2(p_{11}) (1 - 1/p_{11}^2)} \quad (14-47)$$

Expressed in dBi, this is

$$G(\text{dB}) = 20 \log(2\pi a/\lambda) - R_c \quad (14-48)$$

where R_c is analogous to the reduction factor for the sectoral horns described in Section 14.2, "Optimum-Gain Horns," that account for loss in gain due to spherical-wave phase error. The reduction factor is²

$$R_c \approx 0.8 - 1.71(\Delta/\lambda) + 26.25(\Delta/\lambda)^2 - 17.79(\Delta/\lambda)^3 \quad (14-49)$$

TABLE 14-5 Measured and Calculated Gain of Conical Horns

$L (\lambda)$	$a (\lambda)$	Calculated dBi	Expt. (King ²⁹) dBi
8.0	0.7	12.5	12.2
3.5	1.3	16.8	16.5
3.9	1.8	18.0	18.0
3.1	1.8	16.5	16.5
2.8	2.05	12.8	13.2
3.5	1.7	17.5	17.7

where $\Delta = a \tan(\theta_0/2)$. The computed (from Eq. 14-47) and measured gains²⁹ are listed in Table 14-5 for a variety of horn geometries and there is good agreement. The computed gain from CST Microwave Studio for the last horn (i.e., $L = 3.5\lambda$ and $a = 1.7\lambda$) is 17.73 dBi, which is in excellent agreement with King's measured result.

The design of a conical horn for specified beamwidths in the principal planes is performed iteratively. Assume an input waveguide of radius a_w , supporting only the TE_{11} mode. A design procedure is suggested here:

1. Starting with the patterns in Figure 14-20, select a trial value for the radius a to give an approximation to the desired half-beamwidth θ_{bw} in each principal plane. Select a value of horn axial length L , and calculate the length from $h = L(1 - a_w/a)$.
2. Compute the principal plane patterns using Eq. 14-46. Refine a and h to achieve the desired beamwidth.
3. Refine the design further (i.e., input match, polarization, etc.) by simulating the structure with an accurate horn software package.

It happens that for a small-diameter horn in which $a \approx 0.43\lambda$, the E - and H -plane patterns become nearly identical, at least down to the -12 -dB level, providing the wall thickness at the aperture is less than about $\lambda/100$. When the horn aperture terminates in a ground-plane, the diameter is larger for near identical patterns, when $a \approx 0.55\lambda$. In both cases, the half-beamwidth at -12 dB is about 65° and the peak cross-polarization in the intercardinal plane is < -30 dB, which makes the horn suitable as a feed for a reflector having $F/D = 0.4$.

Optimum-Gain Conical Horns

Most of the patterns shown in Figure 14-20 are for horns that are low gain as a result of significant aperture phase error. As mentioned in connection with pyramidal horns, an optimum horn refers to a horn whose aperture radius yields maximum gain for a given length. By means of Eq. 14-46, the maximum gain for a given length can be calculated for a conical horn. To a good approximation $a \approx \sqrt{0.7812 L \lambda}$, which corresponds to $\Delta = 0.39\lambda$, and the maximum gain expressed in dB is $G_{\text{opt}}(\text{dB}) \approx 20.29 \log(a/\lambda) + 12.85$. This means for an optimum conical horn the gain-reduction factor ranges from 2.5 dB to 3.2 dB as the axial length increases from short to long. This range corresponds to aperture efficiencies from 55.7% to 48.2%. Figure 14-22 shows the gain dependence on radius a in greater detail. These curves are historically interesting as King²⁹ gave them in his now classic work on conical horns. The plots differ slightly from the results of the expressions in Eq. 14-46 due to the employment of different methods and approximations in both instances.

Input Match

The input mismatch for conical horn Γ_{in} has similar properties to the pyramidal horn as described in the “Input Match” section within Section 14.2. The mismatch of dominant mode conical horns can be calculated from Eq. 14-30 with the admittance of the TE_{11} mode, given by

$$y_{11} = c_1 \frac{k}{\beta} \int_0^\infty \left(\frac{w\sqrt{1-w^2}}{(ka)^2} \frac{J_1'^2(kaw)}{(w^2 - (p_{11}/ka)^2)^2} + c_2 \frac{J_1^2(kaw)}{w\sqrt{1-w^2}} \right) dw \quad (14-50)$$

where $c_1 = 2p_{11}^4 / (p_{11}^2 - 1)$, $c_2 = 1 / p_{11}^4$, and $p_{11} = 1.841184$. Plots obtained from Eq. 14-50 show that Γ_{ap} is minimum when $ka \sim 3.5$ ($a \sim 0.56\lambda$), which is coincident with the condition for minimum cross-polarization for this mode.⁵⁵ Providing $a > \lambda$, $\Gamma_{ap} < -30$ dB. Design equations for the mismatch at the junction between a circular waveguide feeder and the flare section have been found unreliable. Therefore, it is recommended that once a preliminary design has been made, the horn should be analyzed using an accurate software package to obtain details of other horn characteristics such as mismatch. Suffice to say, the mismatch at the junction is low (< -20 dB) if the flare angle is relatively small ($\theta_o < 10^\circ$). The remedies described in Section 14.2, “Input Match,” can be used, if required, to reduce the mismatch at the junction and aperture.

Other Smooth-wall Circular Horns

Circular geometry has been rich in development of new structures and geometries. Some of these other types of circular horns are mentioned here. Circular corrugated horns are described in Section 14.4.

Coaxial Horns The coaxial waveguide and its horn counterpart are advantageous in some situations because the inside of the inner conductor can be used to support a waveguide or horn for high frequency operation (see Figure 14-23). An example is shown in Figure 14-1e. Such a method of dual-banding is limited to frequencies above the cutoff of the internal conductor. Other bands can be added by inserting additional coaxial waveguides inside successively smaller inner conductors, although it becomes progressively more difficult to feed each horn over a reasonable bandwidth. Letting the inner conductor radius be b and the outer radius be a , the frequency range of the inner conductor is limited to about 10% above the cutoff and bounded at the upper frequency by the TM_{11} mode (i.e., $\sim 2 < kb < 3.83$). Another property of coaxial horns is that the operating bandwidth is slightly higher than a circular horn as the cutoff frequency of the dominant mode is less than that of circular waveguide. This cutoff is approximately given by $k_c a = 2\pi f_c a / c \approx 2/(1 - \tau)$, where f_c is the cutoff frequency and $\tau = b/a$. The bandwidth for TE_{11} mode operation is $2/(1 - \tau) < ka < \pi/(1 + \tau)$.

The main advantage of the coaxial horn is that the parameter τ provides an additional way of varying the radiation pattern, without incurring some phase loss due to the flare angle. Disadvantages of coaxial horns are the high sidelobes and significant aperture mismatch as τ is increased. Above about $\tau = 0.2$, the mismatch can be reduced using a pair of irises; the first one back from the aperture is connected to the outer conductor, and a second iris is connected to the inner conductor

FIGURE 14-23 Geometry of coaxial horn

a farther distance back.⁵⁴ The higher sidelobes and mismatch are due to the annular aperture and the currents on the inner conductor. An approximate radiation pattern for conical coaxial horn is obtained by replacing the Bessel functions in Eq. 14-46 with the function

$$Z_m(x, x\tau) = J_m(x) - \frac{J'_m(x\tau)}{Y'_m(x\tau)} Y_m(x) \quad (14-51)$$

where x refers to the argument of the original Bessel function $J_m(x)$. In addition, p_{11} is now replaced by \bar{p}_{11} , the first root of $J_m(\bar{p}_{11})Y'_m(\bar{p}_{11}\tau) - J'_m(\bar{p}_{11}\tau)Y_m(\bar{p}_{11}) = 0$. These replacements also apply to the aperture admittance of the TE_{11} mode given by Eq. 14-50, where in addition the derivative of Eq. 14-51 (taken with respect to the first argument of $Z_m(x, x\tau)$ only) is also required. The maximum gain is computed from Eq. 14-47, wherein the denominator is replaced by $Z_1^2(\bar{p}_{11}, \bar{p}_{11}\tau)(1 - 1/\bar{p}_{11}^2) - \tau^2 Z_1^2(\bar{p}_{11}\tau, \bar{p}_{11}\tau)(1 - 1/(\bar{p}_{11}\tau)^2)$.

The H -plane beamwidth is approximately the same as for a conical horn, while the E -plane beamwidth increases with τ . The cross-polarization properties are similar to a circular waveguide except that the peak in the intercardinal plane increases, while the ka for minimum cross-polarization decreases with increasing τ . For a coaxial horn with a large flange, this condition is approximately given by

$$ka \approx 3.52 - 1.13\tau - 8.81\tau^2 + 16.34\tau^3 - 8.62\tau^4; \quad \tau \leq 0.8 \quad (14-52)$$

Multimode, Stepped, and Profiled Circular Horns We have seen that for rectangular horns the presence of the higher-order TM_{11} mode in addition to the dominant TE_{11} mode in a conical horn can create a radiation pattern with good axial-beam symmetry and with a low level of cross-polarization as well.¹⁷ When properly phased at the horn aperture, the TM_{11} mode cancels the ϕ -component of magnetic field due to the TE_{11} mode at the aperture boundary, causing H_ϕ as well as E_ϕ to vanish. This is a condition that leads to axial symmetry and low cross-polarization in the radiation pattern. In the original version (called the Potter horn⁷⁷), the TM_{11} mode was generated by a step change in guide radius from r_1 to r_2 in the horn throat, as shown in Figure 14-24. Of course, the radius r_1 must be large enough to support the TE_{11} mode but small enough to ensure that the TM_{11} is cut off (i.e., $1.84 < kr_1 < 3.83$). The amount of TM_{11} generated in this way increases with the ratio r_2/r_1 , but r_2 should not be so large as to permit the TE_{12} mode to propagate ($3.83 < kr_2 < 5.33$). Owing to the axial symmetry, TE_{mn} or TM_{mn} modes with $m > 1$ will not be excited. Figure 14-24 also indicates qualitatively the distribution of the electric field in the aperture for the two modes both individually and in combination. In the central region of the aperture the electric field of the TM_{11} mode reinforces that of the TE_{11} mode. Near the aperture boundary the two fields oppose one another. Thus the resulting electric field may be heavily tapered in the E - and H -planes.

A set of patterns in the E -, H -, and 45-degree planes is shown in Figure 14-25 for a horn with aperture diameter $2a = 4.67\lambda$ and a small semi-flare angle of 6.25° . In this horn $r_1 = 1.02\lambda$, $r_2 = 1.30\lambda$, and $\ell = 0.20\lambda$. The short constant-diameter section of length ℓ is used to ensure that the TE_{11} and TM_{11} modes will be in the same phase at the center of the aperture at the design frequency. This length depends upon the flare angle and the distance from the step to the aperture as well as on the launch phase of the TM_{11} mode relative to the TE_{11} mode.

FIGURE 14-24 Dual-mode horn with generating step and its approximate aperture field distribution

FIGURE 14-25 Radiation patterns of a dual-mode conical horn, $2a = 4.67\lambda$: (a) E -plane, (b) 45-degree copolar, and (c) H -plane (after Potter⁷⁷)

The TE_{11} mode generates θ - and ϕ -components of \mathbf{E} in the far-field, while the TM_{11} mode generates only the θ -component. In terms of the variable $w = ka \sin \theta$ and with the assumption that the aperture is reasonably large ($a \gg \lambda$) so that the reflection coefficient $\Gamma_{in} \approx 0$, the radiated far-field components are

$$E_{\theta} = \left[1 + \frac{\beta_{te}}{k} \cos \theta - \alpha \frac{\beta_{tm}/k + \cos \theta}{1 - (3.83/w)^2} \right] \frac{J_1(w)}{w} \cdot \cos \phi \quad (14-53a)$$

$$E_{\phi} = \left(\frac{\beta_{te}}{k} + \cos \theta \right) \frac{J'_1(w)}{1 - (w/1.84)^2} \cdot \sin \phi \quad (14-53b)$$

where $\beta_{te} = k\sqrt{1 - \left(\frac{1.84}{ka}\right)^2}$ and $\beta_{tm} = k\sqrt{1 - \left(\frac{3.83}{ka}\right)^2}$ refer to the propagation constants of the TE_{11} and TM_{11} modes respectively, and α , the mode-content factor, is a measure of the field strengths of the two modes at the aperture center. For $\alpha = 0.65$ the E - and H -plane HPBW's are equalized, and the phase centers in the planes are coincident. Other values of α , in the neighborhood of 0.6, lead to suppression of the first sidelobe in the E -plane or to suppression of the cross-polar radiation in the intercardinal planes. The presence of the TM_{11} mode has no effect in the H -plane, where this mode does not radiate. The beam-width of a dual-mode conical horn will vary somewhat with the mode-content factor; typically $HPBW \approx 36\lambda/a$.

Mode conversion at a discontinuous step in a round waveguide has been investigated theoretically and experimentally.¹²⁶⁻¹²⁷ Figure 14-26 shows the mode conversion coefficient and excitation phase of the TM_{11} mode relative to the TE_{11} mode on the guide center-line in the plane of the step at $z = 0$. If ϕ_{ex} represents the launch phase, ϕ_{ph} represents the differential phase in the constant-phasing section, and ϕ_{fl} represents the differential phase of the modes in the flared section of Figure 14-24, then the condition for reinforcement of the electric fields at the aperture center is

$$\phi_{ph} + \phi_{fl} - \phi_{ex} = 2m\pi, \quad m = 0, 1, 2, \dots \quad (14-54)$$

where

$$\phi_{ph} = \ell(\beta_{te} - \beta_{tm}) \quad (14-55)$$

FIGURE 14-26 Mode conversion coefficient C and launch phase of TM_{11} mode relative to TE_{11} at step discontinuity (TM_{11} lags TE_{11}) (after Agarwal and Nagelberg¹²⁶ © IEEE 1970)

where β_{te} and β_{tm} depend on the radius r_1 of the phasing section. In the flared horn, the differential phase shift is closely given by

$$\phi_{fl} = \int_{z=\ell}^{z=\ell+h} (\beta_{te}(z) - \beta_{tm}(z)) dz \quad (14-56)$$

in which the guide propagation constants are now functions of the axial coordinate z and h , the length of the flare section. Note that ϕ_{ph} and ϕ_{fl} are positive angles because $\beta_{te} > \beta_{tm}$. These equations have been computed by Potter⁷⁷ and are reproduced in Figure 14-27. In the case of $a/\lambda = 2.33$, the z coordinate has been eliminated by introducing the semi-flare angle θ_f .

As an example of the use of these design curves, consider the horn whose patterns are given in Figure 14-25. With $a/\lambda = 2.33$, $r_2/\lambda = 0.65$, and $\theta_f = 6.25^\circ$, Figure 14-27a gives $\phi_{fl} \approx 625^\circ$, while a phasing section (r_2/λ) of length $\ell/\lambda = 0.25$ from Figure 14-27b gives $\phi_{ph} \approx 50^\circ$. The expected excitation phase is obtained from Figure 14-26; $\phi_{ex} \approx -45^\circ$ for $r_2/r_1 \approx 1.27$. When these values are substituted into Eq. 14-54, the equation is satisfied with a small error. From the same figure, the TM_{11} -mode conversion coefficient appears to be about -7.5 dB; evidently this corresponds closely to the value $\alpha = 0.6$ for the mode-content factor defined in Potter.⁷⁷

The phasing condition of Eq. 14-54 can be satisfied only at a single frequency because of the different dispersion characteristics of the two modes. Thus the dual-mode horn is frequency-sensitive (the horn in Figure 14-25 has a useful bandwidth of only 3 to 4 percent), and the sensitivity increases with horn length, which is typical for such horns. For horns that are not too long, some improvement can be obtained by loading the step discontinuity with a dielectric ring.¹²⁸

Use of a step discontinuity near the horn throat is not the only way to convert TE_{11} to TM_{11} energy in a horn. A technique described by Satoh¹²⁸ employs a thin dielectric band

FIGURE 14-27 Differential phase shifts in (a) the flared horn and (b) the phasing section (after Potter⁷⁷)

placed internally in contact with the horn wall. When the length of the band, its thickness, and its position are correctly determined, the resulting bandwidth of this dual-mode horn is reported to be 25% (defined so that all sidelobes are less than -20 dB and E - and H -plane beamwidths differ by no more than 5%).

Conversion from the TE_{11} mode to the TM_{11} and other higher modes (TE_{12} , TM_{12} , TE_{13} , ...) at a relatively large-diameter junction between round and conical waveguides has been investigated analytically by Tomiyasu.¹²⁹ In this case, a discontinuous step (as in Figure 14-24) is not needed. Using this technique, Turrin¹³⁰ designed multimode horns of the type shown in Figure 14-28. The input guide is sized to propagate in the TE_{11} mode but not the TM_{11} mode ($1.84 < ka_w < 3.83$). Conversion takes place at the plane AA' in Figure 14-28, where the radius a is large enough to support this mode (i.e., $ka > 3.83$). The next-higher modes with the proper symmetry are the TE_{12} mode, which requires $ka > 5.33$, and the TM_{12} mode, requiring $ka > 7.02$. Since these modes are not wanted, the aperture diameter should be restricted so that $3.83 < ka < 5.33$ (i.e., $0.61 < a/\lambda < 0.85$).

At the plane AA' in Figure 14-28, the higher-order TM_{11} mode is 90° out of phase with the TE_{11} mode; hence, the phasing section ℓ should have a differential length of 270° for the two modes to ensure correct phasing at the aperture, thus

$$\ell(\beta_{te} - \beta_{tm}) = 3\pi/2 \quad (14-57)$$

FIGURE 14-28 Stepless dual-mode horn (after Turrin¹³⁰ © IEEE 1967)

To ensure that the correct amount of TM_{11} relative to TE_{11} power is generated at the conical junction, the flare angle θ_f should be chosen to satisfy

$$\theta_f = 22.3\lambda/a \text{ degrees} \quad (14-58)$$

This simple equation comes from equating two different expressions for the mode power ratio, both given in Turrin.¹²⁹⁻¹³⁰ If Eq. 14-57 and Eq. 14-58 are applied to the two horn designs of Turrin,¹³⁰ they predict $\ell = 1.42\lambda$ and $\theta_f = 34^\circ$ for one horn, and $\ell = 3.86\lambda$ and $\theta_f = 24^\circ$ for another horn, in reasonably good agreement with the actual values.¹³⁰ Small horns constructed in accordance with these principles appear to yield a useful bandwidth of about 12%.

There is conversion of power from the TE_{11} mode to TM_{11} mode at the aperture of the horn in Figure 14-24 as well as at the step (also refer to “Multimode, Stepped, and Profiled Rectangular Horns”). The TM_{11} mode generated at the aperture is in quadrature with the TE_{11} component, and its amplitude is not negligible unless the flare angle is very small. The existence of two physically separate sources of TM_{11} -mode generation complicates the design of these horns, and recourse to empirical adjustment of step size and phasing length is usually necessary.

The methods described here can also be applied to conical coaxial horns. An example of the design and test of a Potter-type coaxial horn for a dual-band satellite application is described in James et al.⁵⁶ The difference compared with a circular conical horn is principally the higher sidelobe levels. The operating bandwidth in the lower frequency range is typically only a few percent.

The multimode circular horns described earlier are relatively narrowband. Wider-band horns can be designed by stepping the diameter upward in sections and flaring to the aperture using several axial corrugations. One example is shown in Figure 14-29. The aperture of this horn is relatively small and is suitable for feeding reflectors with $F/D \sim 0.4$. An edge illumination of -12 dB and lower is possible in both principal planes with good axial symmetry and, therefore, low cross-polarization over a 47% bandwidth (*input match* < -20 dB from 1.3 to 2.1 GHz). Through the selection of a number of internal axial corrugations (internal short-circuited ringslots) a combination of TE_{11} , TM_{11} , and TE_{12} modes is

FIGURE 14-29 Stepped circular waveguide with axial corrugations for operation from 1.3 to 2.1 GHz. Dimensions are in mm.

FIGURE 14-30 Computed radiation patterns at 1.75 GHz for the horn shown in Figure 14-29

produced in the aperture. These modes are supported by the TE_{11} mode in the coaxial corrugations. An example of the pattern produced in the intercardinal plane at the center of the band is shown in Figure 14-30, which has been computed using mode-matching software. At this frequency, the magnitude of the amplitudes of the TE_{11} , TM_{11} , and TE_{12} modes in the aperture are in proportion of 1:0.42:0.07 respectively. Toward the upper end of the band, the proportion becomes 1:0.54:0.19. The aperture radius is 150 mm, and the two axial corrugations are set back 10 mm from the aperture. The steps from the input to the axial corrugations are selected for the best input match from, in this case, a 72-mm input radius circular waveguide. The axial corrugations are chosen so that the innermost slot is 0.375λ deep at the center frequency, and the depth of the slots should reduce to about 0.25λ as the input of the shorted axial corrugations approaches the aperture. The end of the corrugations can be tapered linearly or have another shape (e.g., spherical). However, two axial corrugations are usually sufficient in many feed applications and little is gained with more than four. The geometry in Figure 14-29 can be scaled for operation in other frequency bands (i.e., scale the geometry by the factor $1.7/(\text{new center frequency in GHz})$).

Another similar horn is the Scrimp horn invented by Wolf⁸⁴ that is shown in Figure 14-31. This horn was originally developed for feed arrays onboard satellites. It has excellent aperture efficiency ($> 80\%$), an operating bandwidth of about 20%, low cross-polarization, and moderate sidelobe levels. There are three main parts to the Scrimp horn⁸⁴: a conical horn input section, a shorted coaxial waveguide, and a cylindrical output waveguide of length ℓ_c leading to the aperture. The input is a circular waveguide of diameter between 0.75λ to 0.95λ . When a TE_{11} mode is incident on the conical horn section, a standing wave is created in the coaxial waveguide section, which is dominated by a TE_{11} mode. The flare angle θ_c of the horn lies typically between 15° to 25° , and the length of the coaxial waveguide is $\ell_c \approx 0.25\lambda$. The TE_{11} mode in the conical horn oscillates in odd phase to the TE_{11} mode in the output section, and to ensure continuity of the fields additional higher-order modes, mainly TM_{11} and TE_{12} , are generated. These modes

FIGURE 14-31 Geometry of the Scrimp horn

are superimposed on the fundamental TE_{11} mode to produce a field distribution in the aperture that is low in cross-polarized field components. The length ℓ_z is the projection of the flare to the aperture (i.e., $\ell_z \approx (a - r_i) \tan \theta_z$, although this length requires fine adjustment at each value of a to achieve the desired performance). The aperture diameter $2a$ can be between about 1.2 to 1.8λ depending on the desired aperture field taper.

An extension of the concept of tailoring the mode content in the aperture to synthesize a desired radiation pattern is to modify the profile of the horn between the input waveguide and output aperture. Several ways have been tried to control this process, although mostly they entail the use of an optimization method to carry out the changes necessary given a particular representation of the profile. The method of Deguchi et al⁶⁹ represents the horn as a sequence of cylindrical sections where the radius and length of each section is optimized to achieve the desired performance. Another approach, developed by Granet and Bird⁶⁸ and applied to smooth-wall horns by Granet et al,⁷⁰ represents the profile with cubic-splines, and the coefficients of the spline functions are optimized to meet specifications on the radiation pattern and input match. The profile is represented by only a few nodes to produce the spline, in particular two end nodes and five inner nodes. Only seven nodes are used to limit the number of optimization parameters to simplify the optimization process. Letting p_{jk} ($j = 1, \dots, N_p$) represent the power in the copolar pattern in direction j at frequency k ($k = 1, \dots, N_f$) and similarly q_{jk} is the power in the cross-polar pattern. Allow p_{ujk} and p_{ljk} to represent the upper and lower bounds on the copolar pattern and q_{djk} to specify the upper bound on the cross-polar level. Also, let Γ_k and Γ_{dk} denote the input reflection coefficient and the upper bound on reflection at frequency k . The aim of the optimization is to minimize a performance index based on the function

$$f_i = \begin{cases} \alpha_{ujk}(p_{jk} - p_{ujk}), i = 1, \dots, N_s; j = 1, 2, \dots, N_r; k = 1, 2, \dots, N_f \\ \alpha_{ljk}(p_{ljk} - p_{ljk}), i = N_s + 1, \dots, 2N_s; j = 1, 2, \dots, N_r; k = 1, 2, \dots, N_f \\ \alpha_{xjk}(q_{jk} - q_{djk}), i = 2N_s + 1, \dots, 3N_s; j = 1, 2, \dots, N_r; k = 1, 2, \dots, N_f \\ \alpha_{rk}(\Gamma_k - \Gamma_{dk}), i = 3N_s + 1, \dots, N_o; k = 1, 2, \dots, N_f \end{cases} \quad (14-59)$$

where $N_s = N_r N_f$, $N_o = 3N_s + N_f$, $i = 1, \dots, N_o$, α_{ujk} , α_{ljk} , etc., are weighting factors on the copolar, cross-polar, and reflection coefficient responses. There are many ways of seeking zero or negative values for f_i , such as the least p-th index and genetic algorithms. The least p-th index was used in conjunction with Fletcher's quasi-Newton search method by Granet and coworkers^{68,70} and found effective. By these means, circular horns with many different properties can be designed. For example, a horn with a gain of about 25 dBi has been designed to operate over a 50% bandwidth.⁷⁰ The horn profile is shown in Figure 14-32 and the measured and calculated results for a horn developed for the 100-GHz band is given in Figure 14-33.⁷⁰ The profile is close to a $\sin^{3/4}$ -profile followed by a Gaussian profile extension (shown as a dotted line in Figure 14-32). The performance of this horn compares favorably with the more complicated corrugated horn, which turns out to have a shorter length and the radiation patterns to have lower sidelobes. However, smooth-wall horns are simpler to manufacture, especially at high frequencies, and in some applications their performance may suffice.

As we have seen, the Gaussian⁶⁶ (also called *hyperbolic*⁶⁵) profile is very useful for completing the transition of the horn flare from the mid-range matching section to the aperture. Also, it results in compact horns compared with a linear taper. This profile is defined as a function of axial distance (z) and is given by

$$a(z) = a_i \sqrt{1 + \left(\frac{z}{L_p}\right)^2 \left(\left(\frac{a_o}{a_i}\right)^2 - 1 \right)} \quad (14-60)$$

FIGURE 14-32 Profile of smooth-wall horn designed using splines and optimization. Dimensions are given mm.

where a_i is the radius of the input section, a_o is the aperture radius, and L_p is the length of the profiled section.

Dielectric-lined Conical Horns A conical horn with dielectric loading, as shown in Figure 14-34, is capable of operating over very wide bandwidths. A low-dielectric permittivity material or air, with permittivity ϵ_{r1} , between a core of permittivity ϵ_{r2} and a metallic wall allows the creation of a hybrid HE_{11} mode that has very attractive radiation properties, such as good axial symmetry, low sidelobes, and low cross-polarization. There is an optimum gap width t between the core and the wall, and this is given approximately by⁴⁷

$$t \approx \frac{\lambda}{4\pi\sqrt{\epsilon_{r2} - \epsilon_{r1}}} \ln \left(\frac{\sqrt{\epsilon_{r2}} + \sqrt{\epsilon_{r1}}}{\sqrt{\epsilon_{r2}} - \sqrt{\epsilon_{r1}}} \right) \quad (14-61)$$

The hybrid-mode of a conical horn has a low frequency cutoff determined mainly by the permittivity of the core, and the upper frequency is limited by the cutoff of the EH_{12} mode.⁴⁵ This means the performance can be extremely wideband, as much as in excess of 30:1,⁴⁹ although as one might expect, performance is not constant over the band and the beamwidth reduces with increasing frequency.

FIGURE 14-33 Radiation patterns in the intercardinal plane of the horn shown in Figure 14-32 at 107 GHz (after Granet et al⁷⁰ © IEEE 2004)

FIGURE 14-34 Geometry of dielectric-loaded conical horn

The literature describes many different types of dielectric-loaded circular horns.^{45–51} The horn can have a solid-core dielectric with a permittivity of about 2.5 or foam materials with permittivity close to 1. However the widest bandwidth horns use a dielectric permittivity of between 1.1 and 1.2 for the inner core and also a thin-air gap given by Eq. 14-61.

Loss in a dielectric horn can be significant if the material properties are not carefully selected. A simulated permittivity can be made to achieve the desired permittivity by placing regular holes in a selected material such as PTFE, loading a polystyrene foam with small high permittivity spheres, or using alternating layers of low- and high-permittivity materials.⁵⁰ Care must be taken to ensure symmetry is not lost by this approach (equivalent to introducing anisotropy) or that the glue used to bind the materials is not contributing unnecessary loss.

14.4 CORRUGATED HORNS

For many years after the introduction of microwave frequencies, the smooth-wall circular and rectangular horns were the only known types. However, during the 1940s and 1950s the benefits of corrugating surfaces became apparent. Kay¹ was the first to describe a conical corrugated horn and shortly afterward, simultaneously research teams in the United States³⁴ and Australia³⁵ announced publicly the beneficial effects of transverse corrugations on the performance of circular horns. This led to detailed study of corrugated horns⁴¹ that continues to this day. This section summarizes the important information for the design of corrugated horns of circular and rectangular cross-section. We begin with a tutorial on corrugated surfaces.

Hybrid Modes: Soft and Hard Surfaces

A mode in a structure such as a waveguide or a horn that has non-zero field components in the direction of propagation is called *hybrid* to distinguish it from the usual TE or TM modes in hollow pipes. Natural structures, such as dielectric rods, support only hybrid modes. There are also a multitude of other structures that support hybrid modes that occur as a consequence of requiring axial-beam symmetry, low sidelobes, and low cross-polarization. These properties can be obtained with some structures over a wide frequency range (16:1 or more) in a conical horn or open-ended round waveguide that supports the hybrid HE_{11} mode. This mode is a mixture of TE_{11} and TM_{11} modes of the form $TM_{11} + \gamma TE_{11}$, where γ is called the mode-content factor. The waveguide wall presents an impedance to the fields, which is a pure

reactance in the lossless case. Surface impedances are defined for a direction parallel to the surface, say ζ , as follows:

$$Z_{\zeta} = \frac{\hat{\zeta} \cdot \mathbf{E}}{\mathbf{H} \cdot (\hat{n} \times \hat{\zeta})} \bigg|_{\text{surface}} \quad (14-62)$$

where \hat{n} is the normal to the surface and orthogonal to $\hat{\zeta}$. For the most desirable horn performance, the inner surface of the horn or guide must be anisotropic in such a way that it has different reactances, X_{ϕ} and X_z in the azimuthal and z -directions. When these conditions are realized, the TE and TM components become locked together as a single (hybrid) mode, and they propagate with a unique common velocity.

Such an anisotropic impedance can be achieved by cutting circumferential slots into the surface of a metallic waveguide. Thus, in Figure 14-35, which represents a longitudinal section through a cylindrical corrugated waveguide, E_{ϕ} will be zero on the surface of the teeth at $\rho = a$. Each slot acts as a radial transmission line that is short-circuited at $\rho = a + d$. If the line length $d = \lambda/4$, then an open circuit appears across each gap at $\rho = a$. Providing there are several slots per wavelength, then the conditions $X_{\phi} \rightarrow 0$ and $X_z \rightarrow \infty$ will be realized in an average sense. The open-circuit gaps ensure that no axial current can flow at $\rho = a$. Consequently, the azimuthal magnetic field component, which induces axial current flow, is zero. On average, the same boundary conditions now prevail for both azimuthal field components and, therefore, $E_{\phi} = 0$ and $H_{\phi} = 0$ on the guide walls. This condition on the aperture field of a horn leads to axial symmetry and low cross-polarization in its radiation pattern.

The hybrid mode in the waveguide has the cylindrical electric field components

$$e_{\rho}(\rho, \phi) = -j \left[\frac{\beta}{k} J_1'(k_{\rho} \rho) + \gamma \frac{J_1(k_{\rho} \rho)}{k_{\rho} \rho} \right] \cos \phi \quad (14-63a)$$

$$e_{\phi}(\rho, \phi) = j \left[\frac{\beta}{k} \frac{J_1(k_{\rho} \rho)}{k_{\rho} \rho} + \gamma J_1'(k_{\rho} \rho) \right] \sin \phi \quad (14-63b)$$

$$e_z(\rho, \phi) = \frac{k_{\rho}}{k} J_1(k_{\rho} \rho) \cos \phi \quad (14-63c)$$

where $\exp(-j\beta z)$ is understood, and β and k_{ρ} are the propagation constants in the z and ρ directions, respectively, and are related by $\beta^2 + k_{\rho}^2 = k^2$. The magnetic field components can be found from Maxwell's equations in the usual way. It is noted that the ratio of the

FIGURE 14-35 Corrugated circular waveguide with TE_{11} -mode excitation

axial field components is $e_z/h_z = \gamma$. Expressed in rectangular coordinates, the transverse electric field components are

$$e_x(\rho, \phi) = \frac{E_o}{2} [(1 + \gamma k/\beta) J_0(k_\rho \rho) - (1 - \gamma k/\beta) J_2(k_\rho \rho) \cdot \cos 2\phi] \quad (14-64a)$$

$$e_y(\rho, \phi) = -\frac{E_o}{2} (1 - \gamma k/\beta) J_2(k_\rho \rho) \sin 2\phi \quad (14-64b)$$

where $E_o = j\beta/k$. It is clear that the field will be polarized in the x -direction only (i.e., zero cross-polarization) if $\gamma = \beta/k$. Furthermore, this condition ensures that e_x tapers radially with ρ but does not vary with ϕ . However, if $\gamma = -\beta/k$, the transverse field is a mixture of e_x and e_y with strong azimuthal variations.

To satisfy the condition $X_\phi = 0$, $E_\phi = 0$ at $\rho = a$, and then Eq. 14-63 gives

$$\gamma = -\frac{\beta}{k} \cdot \frac{J_1(k_\rho a)}{k_\rho a J_1'(k_\rho a)} = \frac{\beta}{k} \cdot \frac{J_2(k_\rho a) + J_0(k_\rho a)}{J_2(k_\rho a) - J_0(k_\rho a)} \quad (14-65)$$

Thus, it is observed that the condition $\gamma = \beta/k$ occurs at the roots of $J_0(k_\rho a)$ (i.e., for $k_\rho a = 2.4048, 5.5201, 8.6537, \dots$ corresponding to the HE_{1n} ($n = 1, 2, 3, \dots$) modes, respectively). The alternative condition $\gamma = -\beta/k$ occurs at the roots of $J_2(k_\rho a)$ (i.e., for $k_\rho a = 0, 5.1356, 8.4172, \dots$, and these modes are designated EH_{1n} ($n = 0, 1, 2, \dots$), respectively).

The longitudinal reactance X_z (which is infinite at the slot resonant frequency) is obtained from Eq. 14-62 as $jX_z = e_z / h_\phi|_{\rho=a}$. Hence, from Eq. 14-63

$$X_z/\eta = \frac{-k_\rho^2 a J_1(k_\rho a)}{k k_\rho a J_1'(k_\rho a) + \gamma \beta J_1(k_\rho a)} \quad (14-66)$$

where η is the free-space wave impedance. Combining Eqs. 14-65 and 14-66 gives

$$\frac{1}{\gamma} - \gamma = \frac{k_\rho^2 a}{\beta} \cdot \eta/X_z \quad (14-67)$$

Consequently, in the special case of resonant slots ($X_z = \infty$), it follows that $\gamma = \pm 1$. This is called the *balanced hybrid condition*, and, therefore, $\gamma = 1$ for HE modes and $\gamma = -1$ for EH modes. Because Eq. 14-67 is a quadratic in γ , it has two roots in the general case and the designations HE and EH still apply even under unbalanced conditions. The characteristic equation for HE or EH hybrid modes is obtained from Eq. 14-66 by substituting for γ in Eq. 14-65. The surface reactance is capacitive over most of the preferred operating range of the corrugated horn from about where $X_z = \infty$ to $X_z = 0$.

The characteristic equation for the m -th order HE_{1n} mode⁴¹ is

$$\Lambda_n(k_\rho a) - \left(\frac{n\beta}{k}\right)^2 = \left(\frac{k_\rho}{k}\right)^2 S_n(ka, k(a+d)) \quad (14-68)$$

where a is the inner radius of the corrugated waveguide, $a+d$ is the radius to the base of the slot (see Figure 14-35), $\Lambda_n(x) = x J_n(x)/J_n'(x)$, and a function related to the surface admittance presented by the slots at $\rho = a$ given by⁴¹

$$S_n(x, y) = x \frac{J_n'(x) Y_n(y) - J_n(y) Y_n'(x)}{J_n(x) Y_n(y) - J_n(y) Y_n(x)} \quad (14-69)$$

FIGURE 14-36 Slot depth d at resonance (after Thomas³⁹
© IEEE 1978)

Study of Eq. 14-68 shows that under the desired condition on the transverse field for the dominant mode ($n = 1$), namely $k_\rho a = 2.4048$, is approached asymptotically when the normalized frequency ka is large. In that case, β/k approaches unity, and from Eq. 14-65, γ must approach +1. Further, when ka is large, $k_\rho a$ will be close to 2.4048 even when X_z is far from resonance. This means that $J_0(k_\rho a)$ will be small and that $\gamma k/\beta$ will not depart greatly from unity despite the fact that X_z changes drastically with frequency. This means that the balanced hybrid condition is approximated over a wide range of frequencies of up to about 2.2:1. Operation is limited at the upper end of the band by the appearance of the unwanted EH_{11} mode.

Slot resonance ($X_z = \infty$) occurs when the slot depth d is one-quarter wavelength in the radial line of radii a and $a + d$. This depth $d \approx \lambda/4$ when ka is large, is shown in Figure 14-36. The tooth width t in Figure 14-37 should be small compared with the slot width w , typically $t < 0.2w$, in order to reduce frequency sensitivity. There should be several slots per wavelength, preferably

FIGURE 14-37 Small flare angle corrugated horn: (a) conventional corrugations and (b) ring-loaded slots at the input

four or more, although in wideband horns it is permissible to have only two per wavelength at the high-frequency end of the band.

In acoustics, surfaces are termed either hard or soft on the basis of whether there is intense power flow along the surface or no power flow at all close to the surface. There is an analogous situation for electromagnetic waves.¹³¹⁻¹³⁴ The inner surface of the corrugated horn described previously is an example of a soft surface at the slot resonant frequency. Hard surfaces also exist in electromagnetics. An example is a longitudinally corrugated surface in which the slots are filled with dielectric.

For the corrugated horn, the surface impedances are anisotropic; the field in the horn satisfies the general relationship for axial-pattern symmetry, that is

$$Z_\phi Z_z = -X_\phi X_z = \eta^2 \quad (14-70)$$

This is satisfied only if $Z_z = \infty$, and therefore $h_\phi = 0$ at the surface, as was pointed out previously.

Because both e_ϕ and h_ϕ are zero at the inner surface of the corrugated horn under balanced conditions, the axial component of the Poynting vector at this point must also be zero, and there will be no axial power flow along the surfaces. The corrugated surface is, therefore, soft, and the horn itself is sometimes referred to as a *soft surface horn* or simply a *soft horn*. As indicated previously, the surface reactance conditions for a soft horn are

$$X_\phi = 0 \quad \text{and} \quad X_z = \infty \quad (14-71)$$

By contrast, for a hard surface the conditions are the reverse (dual) of these, namely,

$$X_\phi = \infty \quad \text{and} \quad X_z = 0 \quad (14-72)$$

The above is the condition for a so-called *hard horn*. Further discussion of hard horns is delayed until Section 14.5, in the section "Horns with Hard Surfaces."

Conical Corrugated Horns

The radiation from a conical corrugated horn operating in the HE_{11} dominant mode near the balanced hybrid condition can be obtained from aperture fields given by Eq. 14-64 with a quadratic phase factor given by Eq. 14-5 under the usual assumptions ($\theta_0 < 35^\circ$). The result for the far-fields is

$$E_\theta(r, \theta, \phi) = \frac{jE_o ka}{2} \frac{e^{-jkr}}{r} F_\theta [(1 + \gamma k/\beta)G_0(w) + (1 - \gamma k/\beta)G_2(w)] \cos \phi \quad (14-73a)$$

$$E_\phi(r, \theta, \phi) = \frac{-jE_o ka}{2} \frac{e^{-jkr}}{r} F_\phi [(1 + \gamma k/\beta)G_0(w) - (1 - \gamma k/\beta)G_2(w)] \sin \phi \quad (14-73b)$$

where $F_{\theta,\phi}$ are the obliquity factors, G_m is given by the integral following Eq. 14-46 wherein the argument of the Bessel function p_{11} is replaced by $k_\rho a$, which is found in general from the dispersion relation (Eq. 14-68) for a specified ka , aperture radius, and slot depth d (see Figure 14-36). The other parameters required are $\beta/k = \sqrt{1 - (k_\rho/k)^2}$ and γ , which follow from Eq. 14-65. However, under balanced hybrid conditions $\gamma k/\beta = 1$, and for the dominant mode, $k_\rho a = 2.4048$, allowing Eq. 14-73 to simplify to

$$E_\theta(r, \theta, \phi) = E_o ka \frac{e^{-jkr}}{r} F_\theta G_0(w) \cos \phi \quad (14-74a)$$

$$E_\phi(r, \theta, \phi) = -E_o ka \frac{e^{-jkr}}{r} F_\phi G_0(w) \sin \phi \quad (14-74b)$$

which for a directive beam imply cross-polarization is almost negligible and the copolar main beam is almost axially symmetric for the HE_{11} mode for angles θ close to the axis ($< 50^\circ$). However, the rapid decay of the G_0 function with θ usually means for most horns that the obliquity factors have only a secondary effect on both co- and cross-polarization. This is also true for the higher-order HE_{12} , HE_{13} , ... modes. The balanced EH modes, which correspond to $J_2(k_\rho a) = 0$ and $\gamma = -\beta/k$, radiate with a null in the axial direction ($\theta = 0$) and a state of polarization that may be linear, elliptical, or circular, depending on ϕ . They are almost invariably undesirable in antenna engineering applications.

Universal patterns for the small to medium flare horn under balanced hybrid conditions and large ka are plotted in Figure 14-38. The phase center in the principal planes as a function of $k\Delta$, where $\Delta = a^2/2L$, evaluated under the same conditions is, of course, identical, and the result is shown in Figure 14-6. The curve was calculated from Eq. 14-3 and the phase of Eq. 14-74 between the -12 dB points of the main beam. According to Thomas³⁹ when ka is less than 12, the sidelobe level for a given Δ gradually decreases but the shape of the main lobe is virtually unaffected until ka reaches about 6. For $ka < 6$, the flange at the aperture begins to affect the pattern. The patterns become invalid for $ka < 4$. When the flange affects the pattern shape (i.e., $ka < 6$), a remedy recommended in Thomas³⁹ is to extend the corrugations into the plane of the flange. This will preserve pattern symmetry, but it increases the effective aperture size slightly. The new aperture radius is approximately $a' = a + e/2$, where e is the radius of the curved portion of the flange.

The conical corrugated horn has certain advantages over the dominant-mode pyramidal horn as a gain standard. It is not subject to the small gain uncertainties caused by E -plane edge diffraction; its ohmic loss is very small; and it has considerably lower sidelobe levels than pyramidal and smooth-wall conical horns. The absolute gain of a small-to-medium flare dominant mode corrugated horn is

$$G_{\max} = \frac{4\beta/k (ka)^2 |(1 + \gamma k/\beta) G_0(0)|^2}{\left(1 + \frac{\gamma\beta}{k}\right) \left(1 + \frac{\gamma k}{\beta}\right) (J_0^2(k_\rho a) + J_1^2(k_\rho a)) + \left(1 - \frac{\gamma\beta}{k}\right) \left(1 - \frac{\gamma k}{\beta}\right) (J_2^2(k_\rho a) - J_1(k_\rho a)J_3(k_\rho a))} \quad (14-75)$$

FIGURE 14-38 Universal patterns for small-flare-angle corrugated horns under near-balanced conditions. The parameter is the normalized phase error Δ/λ .

This simplifies considerably under balanced hybrid conditions to

$$G_{\max} = 4(ka)^2 \frac{|G_0(0)|^2}{J_1^2(k_p a)} \quad (14-76)$$

The maximum gain for small flare angles ($\theta_0 \sim 0$) with $k_p a = 2.4048$ is approximately $0.692(ka)^2$, that is an aperture efficiency of 69.2%. The gain (Eq. 14-75) expressed in dBi is

$$G(\text{dB}) = 20 \log(2\pi a/\lambda) - R_s \quad (14-77)$$

where R_s is the gain reduction factor, which is a function of $k_p a$. Some polynomial approximations of R_s as a function of the phase factor Δ at selected values of $k_p a$ are given here¹³⁵:

$$\begin{aligned} 1.3351 - 1.3341(\Delta/\lambda) + 14.874(\Delta/\lambda)^2 - 3.5629(\Delta/\lambda)^3; \quad k_p a = 2.3 \\ R_s \approx 1.6307 - 0.7893(\Delta/\lambda) + 11.667(\Delta/\lambda)^2 - 2.1607(\Delta/\lambda)^3; \quad k_p a = 2.405 \\ 2.0038 - 0.2956(\Delta/\lambda) + 8.2429(\Delta/\lambda)^2 - 0.3715(\Delta/\lambda)^3; \quad k_p a = 2.5 \end{aligned} \quad (14-78)$$

The gain is insensitive to deviations from the zero cross-polar condition, $k_p a = 2.4048$, and this is particularly true in the vicinity of $\Delta \approx 0.48\lambda$.

The radiation pattern of a typical conical corrugated horn is shown in Figure 14-39. The horn is pictured in Figure 14-1d. It has radius $a = 140$ mm, semi-angle = 12.5° , length $h = 560.0$ mm and is fed from a waveguide of radius $a_w = 11.16$ mm.¹³⁶ There are 100 variable depth corrugations with a pitch 6 mm and slot-to-pitch ratio of 0.75. It operates satisfactorily across the band from 10.5 to 14.5 GHz and has a gain of 25.8 dBi at 12.5 GHz. The measured cross-polar level in the band is < -35 dB, and the return loss is > 25 dB. Results computed from Eq. 14-73 for a slot depth of 6.5 mm and by a mode-matching method are shown in Figure 14-39 also.¹³⁶

FIGURE 14-39 Radiation pattern of conical corrugated horn at 12.5 GHz. The horn has radius $a = 140$ mm, length $h = 560.0$ mm, semi-angle = 12.5° , and it is fed from a waveguide of radius $a_w = 11.16$ mm. The solid line represents the E -plane, the broken line the H -plane, and the dashed line is the cross-polar pattern in the 45° plane. No symbol represents the dominant mode model, + represents mode matching, and o the experimental results.

A useful property of corrugated horns is that the radiated field can be expressed as a small number of Gaussian modes. This fact is very helpful in the design of quasi-optical systems for millimeter and submillimeter-waves.¹³⁷ Gaussian modes have a Gaussian function amplitude variation with radial distance from the axis of propagation; the decay depends on the distance z along the beam from the source. The Gaussian distribution is the first term of a Laguerre-Gaussian expansion, which allows the radiated field of a corrugated horn to be expressed as a series of such modes.¹³⁸ The zero-order term of this series for the unidirectional field of the HE_{11} mode under balanced-hybrid conditions has the following Gaussian beam-mode propagation function:

$$e_x(\rho, z') = \frac{w_o}{w(z')} \exp \left[-jk \left(z' + \frac{\rho^2}{2R_c(z')} \right) - \frac{j\rho^2}{w(z')^2} + j\phi_c(z') \right] \quad (14-79)$$

where z' is the distance along the beam, ρ is the distance from the beam axis, $w(z') = w_0 \sqrt{1 + \left(\frac{z'}{z_c} \right)^2}$ is the beam radius, $R_c(z') = \left(z' + \frac{z_c^2}{z'} \right)$ is the radius of curvature of the wavefront, $z_c = \frac{\pi w_0^2}{\lambda}$ is the confocal distance, w_0 is the beam waist radius and $\phi_c(z') = a \tan(z'/z_c)$ is the phase shift. The HE_{11} mode has been normalized for unit power. Let $z' = z + z_a$ where z is the aperture coordinate and z_a is the distance of the Gaussian mode origin to the aperture. It can be shown¹³⁷ that for maximum coupling from the HE_{11} mode to the zero-order Gaussian mode $w(z_a) = 0.6435a$. Also, the radius of curvature $R_c(z_a) = L$. These determinations allow the Gaussian beam for the corrugated horn to be fully specified since now

$$w_0 = 0.6435a / \sqrt{1 + \left(\frac{0.4141\pi a^2}{\lambda L} \right)^2} \quad \text{and} \quad z_a = L / \left[1 + \left(\frac{\lambda L}{0.4141\pi a^2} \right)^2 \right] \quad (14-80)$$

Other horns can be represented in terms of Gaussian modes, although many modes are needed to give an accurate approximation of the beam, which complicates the design. A detailed description of Gaussian beam-mode techniques and applications can be found in Goldsmith.¹³⁷

Optimum-gain Corrugated Horns

In common with the other horns, there is a family of optimum corrugated horns. These horns provide the maximum gain for a given length. From Eq 14-75 and with $k_\rho a = 2.4048$, to a good approximation $a \approx \sqrt{0.976 L \lambda}$, and the maximum gain in dB is $G_{\text{opt}}(\text{dB}) \approx 20 \log(a/\lambda) + 12.06$. The phase factor is $\Delta \approx 0.48\lambda$, which means that for an optimum horn the aperture efficiency is about 40.7%. Near the optimum region, the gain is insensitive both to frequency and to small deviations from the condition $k_\rho a = 2.4048$.

Wide-Flare-Angle Scalar Horn

A wide-flare horn is shown in Figure 14-40, and it is apparent that the path error in the aperture can become quite large. In this case, the expressions in Eq. 14-73 and the patterns shown in Figure 14-38 are no longer applicable. Such a horn nevertheless exhibits axial symmetry and low cross-polarization in its radiation pattern, but pattern calculation becomes more complex, involving spherical rather than cylindrical hybrid modes.^{40-41,45} Note that the slots

are customarily cut perpendicularly to the horn wall, as in Figure 14-40, rather than to the horn axis, as in Figure 14-36a. Under balanced hybrid conditions, the radial dependence of Eq. 14-64 is now approximately $J_0(2.4048\theta/\theta_f)$, which can be used as a basis for initial design. The term *scalar horn* was coined³⁴ to emphasize the fact that the far-zone field can be represented by a single scalar quantity under ideal conditions when there is no cross-polarization. Although this is equally true for the small-flare horn, the term *scalar horn* is usually reserved for the wide-flare case.

A set of universal patterns for scalar horns under near-balanced hybrid conditions obtained by Thomas³⁹ is shown in Figure 14-41. Note that the abscissa is now θ/θ_f , where θ is the far-field polar angle and θ_f is the semi-flare angle of the horn. Since θ/θ_f is independent of frequency, it is clear that the scalar-horn patterns are almost frequency-insensitive. This is in direct contrast to the small-flare-horn case, in which beamwidth is proportional to aperture size ka . The transition is determined by the value of $\Delta = a \tan(\theta_f/2)$. For $\Delta < 0.4\lambda$ the beamwidth is controlled mainly by ka and is, therefore, frequency-dependent. As Δ increases beyond 0.5λ , this dependence is reduced, and when Δ exceeds about 0.75λ , the pattern is almost independent of Δ and hence aperture size, as shown in Figure 14-41; this effect is termed *gain saturation*. These patterns apply for values of θ_f up to about 70° . As Δ increases beyond 0.75λ , the top of the beam flattens and the skirts become steeper. At $\Delta = 1.25\lambda$, there is actually a slight dip in the axial direction. Figure 14-42 shows the effect of Δ on the beamwidth of scalar horns at various power levels relative to the peak. A good rule of thumb is that the beam semi-angle at the -12 -dB level is very close to $0.8\theta_f$ while at the -15 -dB level, it is very close to $0.9\theta_f$ for any Δ between 0.75λ and 1.5λ .

The phase factor Δ has a marked effect on the location of the phase center of the horn, as can be seen in Figure 14-43. When Δ is very small, the phase center is on the horn axis very close to the plane of the aperture. As Δ increases, the phase center moves along the axis toward the throat and eventually becomes fixed at the horn apex for scalar horns with $\Delta \approx 0.7\lambda$. The bars show the effect of a frequency change of $\pm 10\%$. The beam efficiency of scalar horns is high. When $\Delta > 0.75\lambda$, the beam efficiency at the -10 -dB level is greater than 87%, and at the -20 -dB level, it is greater than 98%. This is a valuable asset when such a horn is used as a feed in a reflector antenna since spillover loss will be small.

FIGURE 14-40 Wide-flare scalar horn (after Thomas³⁹ © IEEE 1978)

FIGURE 4.41 Universal patterns for wide-flare scalar horns ($\theta_f < 70^\circ$) with the normalized phase error Δ/λ as a parameter (after Thomas³⁹ © IEEE 1978)

FIGURE 14-42 Effect of normalized phase factor Δ/λ on beamwidth of scalar horns at various power levels relative to beam peak (after Thomas³⁹ © IEEE 1978)

To design a scalar horn with a given beamwidth at some relative power level, say, -6 dB, one determines θ/θ_0 from Figure 14-41. It is apparent that $\theta/\theta_0 \approx 0.6$ in this case and that the parameter Δ/λ may have any value between 1.0 and 1.5. If the desired beamwidth is $2\theta = 60^\circ$, one finds that $\theta_0 = 50^\circ$, and R may lie between 2.8λ and 4.2λ .

Input Match and Slot Design

The input reflection coefficient of a corrugated horn is dominated by the reflection coefficient at the junction of the input waveguide (usually a smooth-wall circular waveguide operating in the dominant mode) and the commencement of the flare.

FIGURE 14-43 Distance of phase center, normalized relative to slant length R from apex (after Thomas³⁹ © IEEE 1978)

The aperture mismatch Γ_{ap} is typically < -30 dB for $a > 1.1\lambda$, and if required, can be approximated by Eq. 14-30, where the self-admittance of the HE_{11} mode under balanced hybrid conditions is

$$y_{11} = \frac{5.783}{(ka)^2} \frac{k}{\beta} \int_0^{\infty} \frac{w(2-w^2)}{\sqrt{1-w^2}} \frac{J_0^2(kaw)}{(w^2 - (2.4048/ka)^2)^2} dw \quad (14-81)$$

where $\beta = \sqrt{k^2 - (2.4048/a)^2}$. The standard design of a corrugated horn starts from the smooth wall-input circular waveguide with a section of about a wavelength long where the depth of the corrugations are gradually decreased from a half-wavelength to a quarter-wavelength deep as the horn is widened. By making the first few slots close to one-half wavelength deep, the reactance X_z will be close to zero, thus minimizing the discontinuity between the smooth conducting boundary and the corrugated wall. At the input, a linear taper can be used for the horn profile, although some other profiles, such as “hour-glass” (sine-squared), have been found more effective. To achieve the widest bandwidth operation, the first four to five slots of the input should commence by making the first slot one-half wavelength deep, then gradually reducing the slot depth until the resonant depth determined from Figure 14-36 is reached at the band-center frequency. If the depth is tapered over a distance of a wavelength or more, the match will remain good over a 1.5:1 frequency range.

The structure of a high-performance wide-band horn can be complex, as described by Thomas et al.⁴² They achieved essentially constant beamwidth, low cross-polarization, and low input reflection over a bandwidth ratio 2.2:1 with a four-section horn. The first section is a smooth-walled, profiled taper from a standard round waveguide to a large-diameter second section that acts as a converter for the HE_{11} mode. This is the most critical part of the horn because it determines return loss and strongly affects generation of unwanted EH-type modes. Ring-loaded slots are employed (Figure 14-37b) for greater bandwidth, and dimensions are optimized independently of the conical output that constitutes the fourth section. This requires the use of an intermediate, or third, section acting as a transition device. In this section, the slot depth and pitch change gradually until resonant depth is reached. There is also a gradual change in flare angle to match that of the output section. It is recommended to use five to ten slots per wavelength and the slot width-to-pitch ratio $w/(w+r) \geq 0.75$ (see Figure 14-37a). In a simpler two stage design consisting of the transition and output sections, the slot depths may be chosen empirically according to⁴⁴

$$d_n \approx \lambda \left[0.4 - \frac{(n-1)}{N_T} \left(0.4 - \frac{1}{4} \exp(2/(5ka_n)) \right) \right]; \quad n = 1, \dots, N_T \quad (14-82a)$$

$$\approx \frac{\lambda}{4} \exp(2/(5ka_n)); \quad n = N_T + 1, N \quad (14.82b)$$

where N_T is the number of slots in the transition from the input waveguide, N is the total number of corrugations, a_n is the radius of the corrugated surface at the n -th slot from the input, and λ is the wavelength at the band-center frequency. To prevent generation of the unwanted EH_{11} mode at the junction of the smooth and slotted guides, the reactance X_z should not be positive. Hence, it is advisable to ensure that the first slot is one-half wavelength deep at the highest frequency in the band. The methodology just described was used to achieve a wideband match for the horn pictured in Figure 14-1d with patterns given in Figure 14-39.¹³⁶ Wider frequency bands can be attained with even greater attention paid to this transition section. One approach that has proven particularly effective is to use ring-loaded slots, which are short-circuited coaxial waveguide slots (see Figure 14-37b).

Constant-width slots present a surface reactance that varies rapidly with frequency and is capacitive over a narrow frequency range. Ring-loaded slots present a capacitive reactance over a considerably wider bandwidth and, in addition, the frequency where $X_Z = \infty$ is lower than conventional slots. The frequency where $X_Z = 0$ depends on the slot ratio h_n/d_n (Figure 14-37*b*). Close to maximum bandwidth of 2.2:1 is possible when⁴² $h_n \approx 2d_n/3$. An empirical formula for the input width of slot n ($n = 1, \dots, N_T$) is⁴² $b'_n = p[0.1 + (n+1)(w'/p - 0.1/N_T)]$ where p is the pitch and w' is the outer width of the ring slot. The depth is now given by Eq. 14.82*b* over the full length of the horn (i.e. $n = 1, \dots, N$). At least five ring-loaded slots are needed for conversion from the input waveguide to conventional slots to realize best performance. James and Thomas⁴² provide further details of the design of ring-loaded slots.

By following the practices just described, it should be possible to obtain an input reflection coefficient $\Gamma_{in} < -18$ dB over a 1.5:1 frequency range in a scalar horn with constant width slots and to do considerably better in a small-flare horn over a narrower frequency range.

Other Corrugated Horns

The conventional transversely corrugated horn with a linear taper is just one type of such horns. Several other varieties in use today are described in the following sections and in Section 14.5, under the headings “Elliptical Horns” and “Horns with Hard Surfaces.”

Compact and Profiled Corrugated Horns The small-flare-angle horn, described earlier, tends to be quite long because Δ , the spherical wave parameter at the aperture, normally should not exceed about $\lambda/4$. Furthermore, while it retains good pattern symmetry over a relatively wide frequency range, the beamwidth varies nearly inversely with frequency. Therefore, it yields high efficiency only over a narrow frequency band. The wide-flare, or scalar, horn achieves nearly constant beamwidth and good pattern symmetry over a wide frequency range (1.5:1 or more) as long as the parameter Δ exceeds about $\lambda/2$. However, it has an aperture diameter considerably larger (by 20 to 25 percent) than the small-flare horn, and this can cause excessive blocking (or the small-flare horn may be too lengthy) when it is used as a feed for a reflector.

These shortcomings are mitigated in the compact, profiled corrugated horn in which the flare angle is not constant. Thus, the horn has an axial profile that is curved rather than following a simple linear taper. Although not essential except in wide-band operation, an input section with ring-loaded slots to effect conversion from the TE_{11} to the HE_{11} mode, followed by a specially chosen profiled section, can achieve a satisfactory performance over a frequency range of 2.4:1 from a horn significantly smaller than the conventional scalar horn. Since the cross-polarization level is not high and beamwidth and phase-center movement are not severe, this compact horn can be recommended as a feed whenever space or weight is at a premium.

As an illustration of a simple compact horn for an offset-fed reflector (half-cone angle 45°), a 12-slot corrugated horn that was designed by the methods of Thomas et al⁴² for the frequency band 10.5 to 14.5 GHz is shown in Figure 14-44. Although the number of corrugations is less than optimum, performance is satisfactory for the application. The input waveguide radius is 9.525 mm, and the aperture radius is $a = 28.92$ mm. Details of the slots are given in Table 14-6. Note that two 1-mm length uniform steps are used to represent the small taper between the slots. The experimental radiation patterns and the ones obtained with a mode-matching method are in excellent agreement and a typical result is shown in Figure 14-45 in the far-field region of the horn. At 12.5 GHz, the peak cross-polarization is about -30 dB and the gain is 15.86 dBi while the input reflection coefficient $\Gamma_{in} < -22$ dB.

20	20.1075	1.0			

The Gaussian profile described by Eq. 14-60 is also useful for the output taper of a compact corrugated horn. It is assumed there are five to ten corrugations per wavelength of depth equal to a quarter-wavelength at the band-center frequency. The middle profile between the input section and the output profile can take on a variety of shapes.

FIGURE 14-45 *H*-plane radiation pattern of the 12-slot conical corrugated horn at 12.5 GHz and a range distance of 710 mm. Solid line is measurement and dashed line is calculated result.

It can consist of several short linear sections,^{45,65} a \sin^2 profile,^{44,67} or Gaussian.^{66,139} However, the most compact horns are obtained by designing the complete profile from the input waveguide to the aperture by using optimization methods such as described in Section 14.3 under the subheading “Multimode, Stepped, and Profiled Circular Horns.” The result of one such design for a feed application is shown in Figure 14-46.⁶⁸

FIGURE 14-46 Spline-profile compact corrugated horn (after Granet and Bird⁶⁸ © ANTEM 2002)

FIGURE 14-47 Radiation patterns of a spline-profile corrugated horn at 11.7 GHz

The aperture radius is $a = 85.8$ mm (4.4λ), and it is 500-mm long (19.5λ), which is a greater than 25% reduction in length from a design with a \sin^2 profile, while achieving a similar performance. The radiation pattern of this horn is given at 11.70 GHz in Figure 14-47 where the gain is 25.3 dBi. This gain is equivalent to an ideal optimum-gain corrugated horn with $a = 4.61\lambda$ and $L = 22\lambda$. However, it is emphasized that the profiled horn has significantly lower first sidelobes, peak cross-polarization level, and input reflection coefficient. The input reflection coefficient is < -25 dB over the 11.7- to 12.25-GHz frequency range. Typical for this type of design, the phase center is reasonably constant (this attribute can be included in the optimization if required) and, in this case, is situated 100 mm from the aperture inside the horn. All computer simulations were performed with a mode-matching method.

Multi-hybrid Mode Horns Additional beam shaping is possible in a corrugated horn by generating higher-order hybrid modes along with the HE_{11} . The desired higher-order modes are the HE_{1n} type ($n = 2, \dots$), all of which have axially symmetric patterns that are free of cross-polarization under near-balanced conditions, i.e., large aperture and $\gamma \rightarrow 1$. However, the higher-order modes have different dispersion characteristics, and this causes such horns to be quite frequency-sensitive.

The two-mode horn utilizes only the HE_{11} and the HE_{12} modes, both of which can be generated by a step discontinuity in the throat of the horn. The smooth-wall input guide supports only the TE_{11} mode, so that $1.84 < ka_w < 3.83$. In the corrugated region beyond the step, the radius is a_0 , and it must be large enough to support the HE_{12} as well as the HE_{11} mode but not so large as to support the HE_{13} mode. This requires $5.33 < ka_0 < 8.54$. Thomas⁷⁸ states that a significant improvement in the match near cutoff can be obtained by a gradual tapered increase in the diameter of the input guide near the step. This does result, however, in a slight reduction in the relative power of the HE_{12} mode for a given diameter $2a_0$ in the corrugated region. The HE_{12} -mode power relative to that of the HE_{11}

mode increases as the ratio a_0/a_w increases; unfortunately, a small amount of the EH_{12} mode is also produced. The presence of this mode is undesirable since it causes a significant increase in cross-polar radiation.

The radius a_0 in the corrugated section should be chosen so that ka_0 is close to 8.54, the cutoff for the HE_{13} mode at the uppermost frequency in the band of interest. If the mismatch at the upper frequency is then too large, the radius a_0 must be decreased somewhat. A compromise also must be made in regard to the TE_{11} input-guide diameter. Large values of input waveguide (ka_w near 3.83) lead to low-input reflection and a low level of the unwanted EH_{12} mode but may not result in sufficient power in the HE_{12} mode. Values between 2.2 and 3.0 for the ratio a_0/a_w have provided satisfactory results.

Because the two modes have different propagation constants, the two-hybrid-mode horn must usually incorporate a constant-diameter ($2a_0$) phasing section before it flares to its final aperture diameter. This section ensures that the modes are in the correct phase at the aperture and is exactly analogous to the use of a phasing section in the dual-mode conical horn of Figure 14-24.

The length of the corrugated flare section to the aperture is such as to antiphase the main lobes of the HE_{11} and HE_{12} radiation patterns; this creates a dip in the resultant pattern in the direction $\theta = 0$ (see Figure 14-48). The phase relationship will change with frequency and so, of course, will the pattern shape. This horn⁷⁹ was designed as a highly efficient feed for a prime-focus reflector antenna having a semi-cone angle of 63° . Similar feeds described by Thomas⁷⁸ have bandwidths of a few percent. The relative power levels in the two modes are about equal.

The pattern in Figure 14-48⁷⁹ has desirable characteristics in earth-coverage use from a satellite in a high-altitude circular orbit because of its rapid decay on the edge-of-coverage.

FIGURE 14-48 Experimental and theoretical patterns of a two-hybrid-mode horn with $ka_0 = 8.17$ (After Vu and Vu⁷⁹ © IEEE 1970)

FIGURE 14-49 The bowl-shaped multimode corrugated horn

A two-mode horn of this kind was designed and tested⁸² for use on Navstar satellites of the Global Positioning System, orbiting at an altitude of 20,200 km. It has a length of 14.7 cm and an aperture diameter of 4.29 cm, which is almost exactly twice that of an optimized single-mode horn. The gain at edge of coverage of 14.3° is a minimum of 15.7 dB over a 2-GHz range in the 44-GHz band. This is 1.7 dB higher than the gain of the optimized single-mode horn at edge-of-coverage, a considerable improvement.

While the previous description has been in terms of two modes only, in reality the horns are capable of supporting more higher-order modes, and, therefore, such horns are more accurately described as *multi-hybrid-mode corrugated horns*. R.F. Thomas and coworkers⁸⁰ developed a dual-hybrid mode horn with very low sidelobes that is ideal as a feed for low-noise applications or on a satellite to provide global coverage from a geostationary satellite (half-power beamwidth of 17.4°). While the electrical performance is satisfactory (e.g., low sidelobes), this horn is very long ($\sim 30\lambda$). An alternative horn that achieves similar performance but is significantly shorter is the “bowl-shaped” horn shown in Figure 14-49.⁸³ This consists of a uniform circular waveguide input, which supports only the TE_{11} mode, a step from smooth-wall to corrugated waveguide, which creates the HE_{1n} modes, and a smooth flare transition, which serves to generate more hybrid modes and to take them from the mode generator to an aperture of the right size to give the required beamwidth. The radius defining the profile of the flare section is⁸³

$$\rho(z) = a_0 + (a - a_0) \sin^p \left(\frac{\pi z}{2L} \right) \quad (14-83)$$

where a_0 is the radius of the mode generator, a is the aperture radius, L is the length of the flare section, and z is the distance along the flare ($0 \leq z \leq L$). In its application to a global-coverage horn from geostationary orbit, an optimum index p of the profile was found to be ~ 0.8 . The mode generator section is designed with a radius of $a_0 \approx 2.2a_w$, where a_w is the radius of the waveguide exciter. When choosing a suitable multi-hybrid-mode design, the best results achieved for the application (first sidelobes < -35 dB and cross-polarization < -40 dB at the center frequency) were for a horn with an aperture diameter of 4.6λ and a total length (including mode generator) of $\sim 5.8\lambda$. The radiation pattern at the center frequency is shown in Figure 14-50. At this frequency, the measured far-field gain of this horn was identical to the calculated value of 20.85 dBi. If still shorter horns are demanded, then there will inevitably be some trade-off in low sidelobe-level performance, although this may not be too severe. Sidelobe levels < -32 dB could be achieved in the far-field of a horn about $\sim 4.5\lambda$ long while ~ -40 dB sidelobes are possible with a $\sim 6\lambda$ -long horn.

FIGURE 14-50 The 45°-plane measured and theoretical Fresnel zone radiation patterns of a bowl-shaped horn with aperture radius $a = 4.6\lambda$ at a distance of 51λ from the aperture

The return losses of the multi-hybrid-mode horn designs are typically > 25 dB and gain is > 20 dBi across a frequency band of $\sim 2.5\%$.

This horn is described as multimode because of the significant number of waveguide modes used to represent the aperture field. It was analyzed with many cylindrical waveguide sections using a mode-matching approach. The power (%) in the highest level modes making up the aperture field involves principally components TE_{11} (76.47%), TM_{11} (21.38%), TE_{12} (1.95%), TM_{12} (0.03%), and TE_{13} (0.05%).⁸³

Rectangular Corrugated Horn These horns have the advantage that patterns can be designed for applications requiring elliptical beam shapes with low cross-polarization. Sectoral and pyramidal horns excited by the TE_{10} mode in a rectangular waveguide may also benefit from the use of corrugations in the broad walls of the horn. The effect of the corrugations is to make the magnetic field small or zero at the electric walls, analogously to the vanishing electric field at the magnetic walls. As a result, the E -plane beamwidth is broadened, and the sidelobes are greatly suppressed.

In a square-aperture horn with corrugations in the electric walls, the E - and H -plane patterns will be very nearly identical, at least to the -20 -dB level, and this can be achieved over nearly a 2:1 frequency range. However, it is restricted to a single polarization, namely, when the E -plane is orthogonal to the corrugated walls.

Rectangular horns with corrugations on four faces^{7-10,41} have been designed with nearly identical patterns in the principal planes for circular polarized radiation with low sidelobes. As with all corrugated horns, the transition from smooth-wall input waveguide to the corrugations is made with a slot depth of a half-wavelength to a quarter-wavelength for a good reflection match. Improved pattern control can be obtained by filling the corners with metal where the corrugations meet.^{8,10} The bandwidth and poor cross-polarization of the rectangular corrugated horn is due to the generation of a higher-mode slow wave, which is predicted in the rigorous analysis of the horn.¹⁰ The bandwidth of a rectangular corrugated horn is typically less than 40%, which is somewhat less than the bandwidth of greater than 70% that can be achieved with a circular corrugated horn. Detailed simulation is necessary to obtain the appropriate mode combination in the aperture for the general case, and the use of accurate simulation software is recommended for any design.

14.5 MISCELLANEOUS HORN STRUCTURES

The horns described in the previous sections are the types most frequently encountered. However, there are many other types of horns, and a sample is described in the following section along with some accessories, such as lenses, that can help improve performance in certain situations.

Elliptical Horns

The beams radiated by an elliptical horn have much in common with smooth-wall rectangular horns, except that now a greater variety of tapers are possible in the E -plane.⁹¹ The dominant mode of the air-filled elliptical horn in which the transverse electric field is parallel to the minor axis (see Figure 14-51) of the ellipse is the TE_{c11} even-order mode. Its orthogonal counterpart, having a transverse electric field parallel to the major diameter, is called an *odd-order mode*. It has been shown that for each even mode there exists an odd mode having the same propagation constant. Furthermore, the two modes will have identical, but non-axially symmetric radiation patterns with orthogonal polarizations. It then follows that if the two orthogonal modes are excited in such a way as to have equal amplitudes and a 90° phase difference, the radiated field will be everywhere circularly polarized.

The description of the radiated field is similar to that for a rectangular horn (see Section 14.2), and some of the results can be carried directly over to elliptical horns. The complication is that the radiated fields for the TE_{c11} even-order mode are given in terms of Mathieu functions.¹⁴⁰ Although more accurate simulation by numerical software bypasses the need of these functions. There are computer subroutines for Mathieu functions¹⁴¹ and some symbolic mathematical software (e.g., Mathematica¹⁴²) include them as embedded functions. When a horn of axial length h and aperture with semi-major and minor dimensions a and b is fed from an elliptical waveguide with semi-major and minor dimensions a_w and b_w , the fields of the dominant mode TE_{c11} mode are

$$E_\theta(r, \theta, \phi) = F_\theta (N_x \sin \phi - N_y \cos \phi) \quad (14-84a)$$

$$E_\phi(r, \theta, \phi) = F_\phi (N_x \cos \phi + N_y \sin \phi) \quad (14-84b)$$

FIGURE 14-51 Geometry of an elliptical horn

where

$$N_x = c_0 \int_0^{\xi_0} \int_0^{2\pi} \left[Ce_1(\xi, q) ce'_1(\eta, q) \sinh \xi \cos \eta + Ce'_1(\xi, q) ce_1(\eta, q) \cosh \xi \sin \eta \right] \\ \times \exp \left[jk \left(\sin \theta (x' \cos \phi + y' \sin \phi) - \frac{1}{2} \left(\frac{x'^2}{L_h} + \frac{y'^2}{L_e} \right) \right) \right] d\eta d\xi \quad (14-85a)$$

$$N_y = c_0 \int_0^{\xi_0} \int_0^{2\pi} \left[Ce_1(\xi, q) ce'_1(\eta, q) \cosh \xi \sin \eta - Ce'_1(\xi, q) ce_1(\eta, q) \sinh \xi \cos \eta \right] \\ \times \exp \left[jk \left(\sin \theta (x' \cos \phi + y' \sin \phi) - \frac{1}{2} \left(\frac{x'^2}{L_h} + \frac{y'^2}{L_e} \right) \right) \right] d\eta d\xi \quad (14-85b)$$

where $c_0 = jk\ell E_0 e^{-jk\ell/2\pi}$; $x' = \ell \cosh \xi \cos \eta$; $y' = \ell \sinh \xi \sin \eta$; $\ell = ae = \sqrt{a^2 - b^2}$; a and b are the aperture semi-major and minor axes lengths; e is the eccentricity; $ce_1(\eta, q)$ and $Ce_1(\xi, q)$ are the normal and modified even Mathieu functions of order one, respectively, on which a prime denotes the first derivative with respect to the first argument; and q is the first zero of $Ce'_1(\xi_0, q) = 0$, where $\cosh \xi_0 = 1/e$, and the cutoff frequency of the dominant mode is $k_{c11} = 2\sqrt{q/\ell}$. The parameters L_e and L_h are the axial lengths in the E - and H -planes (see Figure 14-51), in common with rectangular horns, and are given by equivalent equations to Eq. 14-13. Equation 14-85 must be integrated numerically to obtain the far-fields from Eq. 14-84, which are found to furnish useful design information for directive horns in the vicinity of the main beam with $F_\theta = 1$ and $F_\phi = \cos \theta$, particularly for the H -plane radiation pattern within the limitations of the quadratic phase approximation (e.g., dominant mode, flare angles $< 35^\circ$).

Normally, the patterns in the two principal planes are different for an elliptical horn, usually with a shoulder in the E -plane at about ~ 10 dB and a monotonically decreasing H -plane pattern. Lower sidelobes can be obtained in the E -plane by varying the eccentricity along the horn's length (there is a different quadratic phase factor than in Eq. 14-85). With some geometries, the beam can be made almost symmetrical.⁹⁹

The design procedure for elliptical horns is identical to the methodology described for rectangular horns in the section, "Pyramidal Horns." Optimum-gain elliptical horns are also possible. To a good approximation $a \approx \sqrt{0.94 L_h \lambda}$ and $b \approx \sqrt{0.65 L_e \lambda}$, and the aperture efficiency is $\sim 50\%$ for this family of horns. This means the solution of Eq. 14-25 for an optimum-gain rectangular horn given by Eq. 14-26 is applicable also to an optimum-gain elliptical horn, wherein $\alpha_1 = 0.94\lambda$, $\beta_1 = 0.65\lambda$, $g_1 = 2\pi^2$, and it is understood that a , a_w , and so on, now refer to the corresponding ellipse semi-axes (see Figure 14-51). The H -plane pattern of the optimum horn family has low sidelobes while in the E -plane, the first sidelobe is about -10 dB (compared with -9 dB for a pyramidal horn and ~ -8.5 dB for a conical one).

Elliptical corrugated horns have also proven useful,⁹³⁻⁹⁵ and moderately wideband performance (up to 40%) has been reported through careful design of the transition from the feeder waveguide to the aperture.⁹⁵ The copolar radiation pattern at the balanced hybrid condition can be calculated approximately for initial design purposes from an aperture field for a round corrugated horn given by Eq. 14-64 with a quadratic phase factor¹⁴³ plus information given in the "Input Match and Slot Design" section in Section 14.4 to determine the slot depth and pitch. It is assumed that in the principal planes of the elliptical horn (i.e., the planes containing the major and minor axes) the radiation patterns will be approximately the same as for those of a round horn of corresponding aperture diameters. If ka and kb are moderately large, it is permissible to use constant depth in any one slot, rather than one that varies with the angle ϕ . This greatly simplifies construction of the horn.

Dielectric loading may be used in lieu of corrugations to generate elliptically shaped beams with good circular polarization over a broadband.^{96–98} Both elliptical- and rectangular-aperture horns have been used successfully for this purpose.

Ridged Horns

As we have seen, up to about 2.4:1, bandwidth can be obtained with a corrugated horn by special attention to the input match. When wider bandwidths than this are required, possibly extending over several octaves or even frequency decades, other approaches are needed that ultimately depend on attaining wideband transition from other components such as the feeder. The input match is the usual parameter used to define the operation of ultra wideband, although constant gain performance is sometimes used. The horn patterns vary significantly over wide frequency ranges; nevertheless, a return loss of greater than 10 dB can be achieved over several octaves.

The most common wideband transition is related to the ridged waveguide—double-ridged for single polarization and quad-ridged for dual polarization.²⁴ Waveguides, such as ridged waveguide, with re-entrant cross-sections, have wide frequency separation between the cutoff of the fundamental TE mode and the next higher-order mode. This is due to the constriction between the ridge and the two waveguides on either side of it. Any of the horn types described previously can be used as the radiating element. Rectangular,^{1,24–27} conical,^{33,85–88} and dielectric-loaded horns are the most usual (for example, a quad-ridged conical horn is illustrated in Figure 14-52). Historically, the work of Walton and Sundberg²⁴ on the double-ridge rectangular horn was important and is still in use today for the design of such horns with over a decade frequency range. The aim is to taper the ridges to make a smooth transition from the input (usually a coaxial connection) to the aperture to achieve a good match to the aperture. This is done by ensuring the ridges taper as the horn flares outward. For dominant mode horns, it is common practice to keep the cutoff frequency of the dominant mode approximately constant as the ridged horn flares. It is important that everywhere along the horn the geometry can support the dominant mode at the lowest frequency. Otherwise the mode can become trapped, and although tunneling can occur, there will be significant input mismatch and gain will suffer. The ridge is rolled off from about a quarter of the way down the flare using a common profile such as a \sin^2 or exponential taper (see Figure 14-53). If quad-ridges are used, it is vital to maintain symmetry between the ridges, otherwise cross-polarization will suffer. Mechanical accuracy and good contact of the ridges to the walls is necessary to achieve the widest range of frequencies and best performance. Double-ridge horns can be designed approximately by the methods outlined in Bruns et al²⁶ and the performance tuned by electromagnetic software. A double-ridge horn simulated in this

FIGURE 14-52 Quad-ridged conical horn

FIGURE 14-53 Sectional perspectives of the input to a quad-ridged horn. E1 and E2 refer to the two polarizations.

way gave good agreement with measurement over part of the 1–18-GHz operational range.²⁶ This work showed that at high frequencies, the main beam splits into multiple lobes. A quad-ridged horn with no sidewalls overcomes this problem and operates successfully over the full frequency range.²⁷

The widest bandwidth with a ridge waveguide is made possible when the input ridges are very close together. This narrow spacing of the ridges ultimately determines the lowest frequency for a given geometry. It also means that wideband horns are difficult to construct for the millimeter-wave band. In addition, a reasonable length of taper is required to give wideband performance. If the ridge is too short, mismatch and frequency performance will be poor. It is recommended that the length of the taper should be at least four times the wavelength at the lowest frequency. As a result, wideband feed horns are quite long. If higher than about a –10-dB mismatch loss can be tolerated, the horn length can be shortened significantly for a reduced frequency range. Typically a 1λ length or less horn can give a 3:1 operational bandwidth with a maximum return loss of ~6 dB.²⁵ An example of the input match of a quad-ridged conical horn⁸⁶ is shown in Figure 14-54. The bandwidth of this horn is 10:1, and the return loss across the band is greater than 10 dB.

The radiation pattern can be predicted approximately by neglecting the ridges in the aperture, although in practice the ridges have a second-order effect. The gain of a ridged-waveguide-fed horn can be estimated also from the gain of the corresponding flared geometry. For example, the measured gain of a double-ridge horn is lower than predicted by Eq. 14-15 for a pyramidal horn by 1–2.25 dB.¹⁴⁴

FIGURE 14-54 Measured reflection coefficient of quad-ridged conical horn (after Lai et al⁸⁶ © IEEE 1987) that covers a 10:1 bandwidth

Horns with Hard Surfaces

A horn with a hard surface condition, or hard horn, satisfies Eq. 14-72. This implies that both axial field components vanish at the horn's hard inner surface. For this to occur in a circular geometry, Eq. 14-63 requires that the radial-separation constant k_ρ must be zero and the mode must be TEM. It is then found that the transverse components become

$$e_\rho = -e_\phi = h_\rho = h_\phi = -j(1 + \gamma)/2 \quad (14-86)$$

The value of the mode-content factor γ is quite immaterial in this case compared with the soft horn. If it is zero, then the mode is a degenerate form of TM_{11} ; if it is infinite, it is a degenerate form of TE_{11} . The mode also can be regarded as degenerate HE_{11} if $\gamma = 1$; if $\gamma = -1$, however, all components vanish. The components in Eq. 14-86 show that the Poynting vector is z -directed, constant, and also independent of ρ , as befits a hard surface. Furthermore, Eq. 14-64 indicates that the aperture field is unidirectional containing only the component e_x . In the absence of spherical wave-phase error, this mode radiates with 100% aperture efficiency and -17.6 -dB first sidelobes. By comparison, the ideal soft horn has 69% efficiency, -27.5 -dB first sidelobes, and a half-power beamwidth that is 28% larger than that of the ideal hard horn of the same aperture diameter.¹³²

A horn having longitudinal corrugations approximates the hard boundary condition when the depth of corrugation is⁷⁵

$$d \approx \frac{\lambda}{4\sqrt{\epsilon_{r2} - \epsilon_{r1}}} \quad (14-87)$$

where ϵ_{r1} and ϵ_{r2} are the permittivity of the materials filling the horn and in the corrugations. Note that Eq. 14-87 is identical to Eq. 14-39 for a rectangular horn with dielectric lining on the two E -plane walls (see "Dielectric-lined Rectangular Horns," earlier in the chapter) and, therefore, this latter horn has two hard surfaces. Square horns have been realized with four longitudinally corrugated surfaces filled with dielectric.¹⁴⁵ Longitudinally aligned strips on dielectric can also meet the hard boundary condition when the dielectric thickness satisfies Eq. 14-87. Both filled corrugation and strip-loaded dielectric surfaces work satisfactorily over a relatively narrow bandwidth for any aperture size and shape. The horns tend to have higher efficiency as the aperture size increases due to the power in the wall area decreasing relative to the total power. A circular dielectric-loaded horn can also be designed to have a hard boundary surface.⁵¹ The dielectric load has an inner core of permittivity ϵ_{r1} that has a coat of higher permittivity material (ϵ_{r2}) of thickness t_2 . This coated dielectric load is placed at a uniform distance t_3 from the metallic horn wall. The spacing material has permittivity ϵ_{r3} and is usually air with symmetric dielectric supports to minimize cross-polarization. The material parameters are chosen so that $\epsilon_{r2} > \epsilon_{r1} > \epsilon_{r3}$. The coating thickness for hard surfaces is typically $t_2 < 0.15\lambda$ for $\epsilon_{r1} = 1.3$ and reduces as ϵ_{r2} is increased. The total spacing thickness $t_2 + t_3$ is also lower for high ϵ_{r2} . For example, when $\epsilon_{r1} = 1.3$ and $\epsilon_{r2} = 4$, $t_2 + t_3 \approx 0.31\lambda$. Horns designed with these surfaces have the potential for achieving pattern performance approaching a corrugated horn, although with aperture efficiencies of greater than 90%.⁵¹

Absorber-lined Horns

It has been shown that a conical horn with a lossy dielectric layer (relative permittivity $\epsilon_r = \epsilon'_r + j\epsilon''_r$) can support nearly balanced hybrid modes¹⁴⁶ when the horn diameter is large ($ka \gg 1$). The thickness of the layer and the dielectric-loss tangent should be large

enough to ensure that one-way transmission is attenuated by at least 10 to 15 dB. In this case, the eigenvalue $k_p a$ will be close to the desired value, 2.4048, and it will have a small imaginary part. As a consequence, the propagation constant also will have a small imaginary part, which means that the HE_{11} mode suffers a slight ohmic loss. There is then no upper limit to the frequency of hybrid-mode operation. The absorber thickness decreases as ϵ'_r and ϵ''_r increase, and in a horn with large ka , the field radiated from the absorber annulus will be negligible.¹⁴⁷ A nearly balanced HE_{11} mode operation was first demonstrated in a horn reflector with an aperture diameter of 217 cm by Knop et al.¹⁴⁷ An absorber dielectric with $\epsilon'_r = 1.4$ and $\epsilon''_r = 0.56$ lines the upper part of the cone and enables the horn to operate from 4 to 12 GHz, the upper limit in the frequency being set by the nature of the waveguide launcher at the throat of the horn. The ohmic loss is less than 0.5 dB over the band.

A conical horn lined with magnetically lossy material has been shown to exhibit hybrid-mode operation¹⁴⁸ but at the expense of 10 dB of ohmic loss. In a different version,¹⁴⁹ the loss was considerably reduced, being between 0.8 and 2.7 dB.

Horns with a Protruding Central Conductor

A horn with a central conductor that extends from the aperture is used to support the horn as a feed and in medical probes. Some examples of horns with an extended central conductor are the conical and rectangular horns, Cutler, hat, and cup feeds.^{21–23,59–64} The central conductor can enclose a coaxial cable or waveguide to feed the horn or contain other sensing apparatus. An example of a conical horn with a protruding conductor is shown in Figure 14-55. The diameter of the central rod influences the performance of the horn, and to retain most of the properties of the original horn, the rod radius b should satisfy $kb < 2$ and $b/a < 0.25$, where a is the aperture radius (i.e., $b < 0.3\lambda$ and $a > 1.2\lambda$).⁵⁵ While this can be easily met with a coaxial cable feed, a waveguide feed may need to be dielectric-loaded to keep the rod radius as small as possible. When the conditions above are not satisfied, the H -plane pattern is narrower and the E -plane pattern wider compared with the original horn, increasing the level of cross-polarization.⁵⁵ The horn can be fed directly by the coaxial cable connected to a dipole exciter, a pair of slots, a waveguide reflector at the closed back of the horn or a folded waveguide transition. The exciter can limit the usable bandwidth to only a few percent of the operating frequency if care is not taken with the method of feeding. Wider bands are possible (~20%) using suitably designed excitation. Choke rings in a flange near the aperture can improve the radiation pattern symmetry of small aperture horns ($ka < 4$).⁶²

FIGURE 14-55 A conical horn with protruding central conductor

Horns with Lenses

A lens is sometimes added to a horn, usually at the aperture, to alter the radiation performance to suit the application. This is especially true for correcting phase errors and for realizing significant directivity in a confined length. A dielectric lens is usually preferred as metal plate lenses cause diffraction and depolarization that significantly change the behavior of the original horn. A lens can increase aperture efficiency, reduce sidelobes, or produce a combined phase center that is less sensitive to frequency. There are many different types of lenses for horns based on the surface profile of the inner and outer surfaces.⁴⁵ The most common type for horns is the plano-convex lens (see Figure 14-56), which has plane inner and convex outer surfaces. To simplify design, lenses are mostly circularly symmetric, although elliptical lenses have been produced for elliptical horns. The profile of a plano-convex lens is given by

$$\rho = \frac{\sin \theta (F + (\sqrt{\epsilon_r - 1}t)) + \tan \theta F(\epsilon_r - 1 - \sqrt{\epsilon_r - \sin^2 \theta})}{\epsilon_r - \sqrt{\epsilon_r - \sin^2 \theta}} \quad (14-88a)$$

$$z = \left(\frac{\rho}{\sin \theta} - \frac{F}{\cos \theta} \right) \sqrt{\epsilon_r - \sin^2 \theta} \quad (14-88b)$$

where F is the distance to the focal point, t is the lens thickness, and ϵ_r is the dielectric constant of the lens material. The wavefront from the lens is planar as long as the horn produces spherical waves, which implies that the combined phase center of the radiation is independent of frequency. The lens thickness is given by

$$t = \frac{F}{(\sqrt{\epsilon_r} - 1)} \left(\sqrt{1 + \frac{1}{(2F/D)^2}} - 1 \right) \quad (14-89)$$

where D is the lens diameter. Clearly, the lens is thicker with lower dielectric constant materials, which usually means weight and cost problems in manufacturing and application. To overcome these deficiencies, the lens surface can be “zoned” so the optical path from one

FIGURE 14-56 Geometry of horn with plano-convex lens

most practical purposes.¹⁵⁰ For example, a hyperbolic plano-convex lens (the convex surface is facing the source compared with Figure 14-56), designed for a conical horn for a 60-GHz wireless link,¹⁵¹ gave good performance when zoned, and at the same time, the combination was highly compact. Accurate simulation software should be used to correct for second-order effects.

Dielectric Horns

Solid dielectric horns have additional contributors to the radiation than the metallic horns discussed in the previous sections. There are three basic sources of radiation that need to be included. From the input of the horn, they are the (i) transition from the source (usually a waveguide) to the dielectric, (ii) radiation from the tapered horn as the wave travels toward the aperture, and (iii) radiation from the aperture. Radiation from source (iii) normally provides the greatest contribution. The dominant mode is a hybrid HE_{11} type, and the difficulty of obtaining the field and propagation parameters of this mode, as well as the three-part radiation mechanism, make dielectric horns more complex to design than metallic horns. The directive beam is determined by the aperture and to block radiation from sources (i) and from the tapered horn (ii), the end launcher and flare can be shielded or coated with absorbing material. Solid dielectric horns with conventional geometries, such as pyramidal and conical types, have been designed with some success.^{102–108} Weight can be reduced by hollowing the dielectric as has been described in Palit¹⁰⁷ for a pyramidal horn; the hollowing also lowers the E -plane sidelobes relative to the H -plane. The computed radiation for a dominant mode approximation with the phase-shift variation from the input to the aperture included gave good agreement with experiment. Less conventional feed structures can be employed with dielectric horns, such as a two-wire line and launcher plates,¹⁰⁸ which when applied to a pyramidal dielectric horn, the FDTD method predicts constant input impedance over a 120% bandwidth.

CONTENTS

15.1 INTRODUCTION	15-2
15.2 DIFFRACTION ANALYSIS TECHNIQUES FOR REFLECTOR ANTENNAS	15-3
15.3 CONVENTIONAL REFLECTOR ANTENNAS	15-10
15.4 OFFSET (SYMMETRIC) PARABOLOIDAL REFLECTORS	15-16
15.5 REFLECTORS OTHER THAN PLANE OR PARABOLIC	15-32
15.6 PASSIVE REFLECTORS	15-40
15.7 LARGE-APERTURE REFLECTOR ANTENNAS	15-47
15.8 DIFFRACTION SHAPING	15-57

The original chapter was written by Kenneth S. Kelleher and Geoffrey Hyde.

15.1 INTRODUCTION

Demand for reflector antennas for use in radars, radio astronomy, microwave communications, satellite communications and tracking, remote sensing, and the like has resulted in the development both of sophisticated reflector antenna configurations and of analytical and experimental design techniques. Reflector antennas may take varied configurations, some of the most popular ones being plane, corner, singly and doubly curved, and single and multiple reflectors. The actual configurations used depend heavily on the nature of applications and the resulting radiation patterns such as pencil beam and contour beam, as well as multifrequency and polarizations, etc.

Searching the literature, we see that we can classify reflector antennas in a variety of ways. Reflector antennas can be identified according to *pattern* type, *reflector surface* type, and *feed* type. Pencil-beam reflectors are perhaps the most popular ones and are commonly used in point-to-point microwave communications and telemetry because their patterns yield the maximum boresight gain, and typically their beam directions are fixed at the time of antenna installation. In some applications, such as satellite communication systems, the uplink beam of these pencil-beam reflectors may be either fully steerable by reflector movements, or capable of limited steering. Recent generations of satellite reflectors have produced other popular types of pattern classifications: contour (shaped) beams and multiple beams. These applications require reflectors with improved off-axis beam characteristics, which result in more sophisticated configurations. There are many microwave communication antennas operating with one sense of polarization at a given frequency and require only reasonable discrimination between orthogonal polarizations. However, the current generation of microwave communication and remote sensing antennas operate with dual polarizations at the same frequency to enhance their so-called frequency reuse capabilities or radar polarimetric properties. These requirements necessitate improved polarization performance and could be used as factors in pattern classification.

Performance of reflector antennas cannot be properly examined without knowledge of their feed configurations. Horn or waveguide feeds operating in a single pure mode have been the most popular feeds for reflectors. However, to meet radio astronomy, earth station, and satellite antenna requirements, considerable effort has been focused on the development of new feeds to efficiently illuminate either the main reflector or the subreflector of the antenna. For example, hybrid-mode feeds (combining TE and TM fields) are used to match efficiently the feed distribution with the desired focal field distribution of the reflector, which also results in an ideal feed for reducing cross polarization. Among the hybrid-mode feeds are feeds with corrugated metal walls. Another important consideration is the complexity of the feed system in terms of the number of feed elements used, for instance, to create contour or multiple beams. The proximity of feed elements necessitates an understanding of mutual coupling and the overcoming of difficulties in designing an acceptable beamforming network. Even more recently microstrip patch antennas have been considered as array feeds for reflector antennas. Impulse radiating reflector antennas and compact range reflector antennas require feeds of very wide bandwidths. Due to page limitations, this chapter does not focus on various feeds and their designs. The reader may need to consult other chapters of this handbook or other pertinent references.

The objective of this chapter is to enhance the material in the earlier version of this chapter written by K. Kelleher and G. Hyde¹ and to use updated material and newly generated graphs based on Rahmat-Samii's book chapter² on reflector antennas and recent publications to provide a summary of the performances of many representative reflector antenna configurations as just discussed. Numerous design charts of offset reflector configurations,

which are used extensively in today's reflector antenna designs, are provided. There are a few recently published books, review papers, and collections of papers that the reader is strongly advised to study.¹⁻¹¹ These references provide detailed mathematical, simulation, and measurement results.

15.2 DIFFRACTION ANALYSIS TECHNIQUES FOR REFLECTOR ANTENNAS

The maturity and accuracy of analytical/numerical techniques have allowed reflector antenna engineers to extensively utilize commercial or customized computer programs in the performance evaluation and design of reflector antennas. There are ample successful checks of the results of these techniques against measured data. This section describes the basics of some of the current and popular techniques. As a baseline, dual-offset reflector antennas are used for the description of these techniques.

Figure 15-1 shows the geometry of a dual-offset reflector with a feed arbitrarily positioned. This is a rather general configuration, and all other cases, such as single reflectors, symmetric configurations, Cassegrains, etc., can be regarded as special cases. Reflectors with more than one subreflector (beam waveguide systems) may also be handled by replacing the subreflector of Figure 15-1 with the appropriate beam waveguide systems. To facilitate the discussion, three coordinate systems are erected to define the main reflector, the subreflector, and the feed (or array of feeds) position. The position and field vectors of these coordinate systems can be interrelated using the Eulerian angles construction.^{12,13} Using appropriate coordinate transformations, the fields of a feed can be expressed in feed coordinates (x_F, y_F, z_F), then transformed into subreflector coordinates (x_S, y_S, z_S) to determine the scattered field from the subreflector, and then transformed again into main reflector coordinates (x_M, y_M, z_M) to finally obtain the radiated field of the main reflector.

Among many analytical/numerical diffraction analysis techniques, we can refer to physical optics (PO), aperture field (AF), geometrical optics (GO), geometrical theory of diffraction (GTD), method of moments (MOM), Gaussian beam method, or any combination of these. Clearly, advantages and disadvantages appear when comparing these techniques. Comparisons can be made based on the particular reflector configuration,

FIGURE 15-1 Geometry of a dual-offset reflector antenna with various coordinate systems

far-field pattern domain, polarization, computation time, accuracy, etc. MOM gives the most accurate result, but it is impossible to use it economically for reflectors larger than several wavelengths. The aperture field method is not very accurate for offset configuration with displaced feeds when the edge diffracted rays are not included in the construction of the aperture fields. The GTD method is not easily applied in the caustics regions of pencil beams. The PO method can take an excessive amount of computation time for large reflectors, in particular, in the dual-reflector configuration, etc. Many advances have been reported to improve both the accuracy and the computation time. One of the most appealing techniques has been the application of GTD for the subreflector and physical optics for the main reflector, in conjunction with efficient expansions, such as Jacobi-Bessel, sampling theorem, etc. A summary of some of these techniques that utilize some of the Rahmat-Samii's materials² is provided next.

Physical Optics (PO) Technique

The mathematical formulation of physical optics, or PO, is based on the assumption that the induced current on a perfect electric conductor (PEC) reflector surface is given by

$$\mathbf{J} = \begin{cases} 2\hat{\mathbf{n}} \times \mathbf{H}^i & \text{illuminated region} \\ 0 & \text{otherwise} \end{cases}$$

where $\hat{\mathbf{n}}$ is the unit normal to the surface and \mathbf{H}^i is the incident magnetic field. This incident field may emanate directly from the source or be scattered from the subreflector. Although PO current is an approximation for the true current on the reflector surface (obtainable using MOM), it nevertheless gives very accurate results for far fields of reflectors as small as approximately 5 wavelengths in diameter. The PO current displays certain errors, particularly near the edge of the reflector, which can be augmented by the incorporation of the fringe current. Unfortunately, the incorporation of the fringe current is not in general an easy task, although it may be required to accurately determine the far fields for a very wide range of observation angles, typically near 90° off boresight. The radiated \mathbf{E} field can be constructed using

$$\mathbf{E}(\mathbf{r}) = -\frac{j}{\omega\epsilon} \int_{\Sigma} [(\mathbf{J} \cdot \nabla) \nabla + k^2 \mathbf{J}] g(R) dS' \quad (15-1)$$

which is applicable for both the near- and far-field zones.^{5,14} The preceding expression can be easily derived using the concept of vector potentials. In Eq. 15-1, \mathbf{r}' , \mathbf{r} , and \mathbf{R} are described in Figure 15-2, $k = \omega\sqrt{\mu\epsilon}$, and

$$\begin{aligned} g(R) &= \frac{e^{-jkR}}{4\pi R} \\ \nabla g(R) &= \left(jk + \frac{1}{R} \right) g(R) \hat{\mathbf{R}} \\ (\mathbf{J} \cdot \nabla) \nabla g(R) &= \left[-k^2 (\mathbf{J} \cdot \hat{\mathbf{R}}) \hat{\mathbf{R}} + \frac{3}{R} \left(jk + \frac{1}{R} \right) \right. \\ &\quad \left. \times (\mathbf{J} \cdot \hat{\mathbf{R}}) \hat{\mathbf{R}} - \frac{1}{R} \left(jk + \frac{1}{R} \right) \mathbf{J} \right] g(R) \end{aligned} \quad (15-2)$$

FIGURE 15-2 Reflector geometry for constructing the physical optics (PO) formulation

Further simplification of Eq. 15-1 allows us to obtain the following well-known expression for the radiated field in the far-field zone:

$$\mathbf{E}(\mathbf{r}) = -\frac{jk^2}{\omega\epsilon} g(r)(\hat{\mathbf{I}} - \hat{\mathbf{r}}\hat{\mathbf{r}}) \cdot \mathbf{T}(\theta, \phi) \quad (15-3)$$

$$\mathbf{T}(\theta, \phi) = \int_{\Sigma} \mathbf{J} e^{jk\hat{\mathbf{r}} \cdot \mathbf{r}'} d\Sigma' \quad (15-4)$$

In deriving the preceding expression the standard far-field approximations are used:

$$R = |\mathbf{r} - \mathbf{r}'| \cong r - \hat{\mathbf{r}} \cdot \mathbf{r}'$$

A similar but slightly more complicated expression can also be developed for the field in the Fresnel zone.

The curved surface integration in Eq. 15-4 over Σ can be recast in terms of integration variables defined in a projected planar aperture by properly using the surface projection transformation

$$\mathbf{T}(\theta, \phi) = \int_{\sigma} \mathbf{J}_{\text{eff}} e^{jk\hat{\mathbf{r}} \cdot \mathbf{r}'} dS' \quad (15-5)$$

where

$$\mathbf{J}_{\text{eff}} = \mathbf{J} \sqrt{1 + \left(\frac{\partial f}{\partial x'}\right)^2 + \left(\frac{\partial f}{\partial y'}\right)^2}$$

In Eq. 15-5 σ is the projected aperture in the xy plane, and $z' = f(x', y')$ defines the description of the reflector surface.

The physical optics radiation integral in Eq. 15-5 may be evaluated in many different ways, and its efficient evaluation has been a challenging problem. A successful numerical method has been used based on the small patch constant phase technique,¹⁵ which can be applied to both the subreflector and main reflector geometries. Efficient numerical methods, which are particularly applicable to the main reflector with circular and elliptical

projected apertures, have been developed in Rahmat-Samii and Galindo-Israel¹⁶ and in Galindo-Israel and Mittra.¹⁷ One of these methods, which is based on the Jacobi-Bessel expansion, is particularly effective when it is used to evaluate Eq. 15-5. It can be shown that, based on this expansion, the radiation integral can be expressed as¹⁶

$$T \propto \sum_{p=0}^{P \rightarrow \infty} \frac{1}{p} (jk)^p (\cos \theta - \cos \theta_B)^p \sum_{n=0}^{N \rightarrow \infty} \sum_{m=0}^{M \rightarrow \infty} J^n [{}_p C_{nm} \cos n\phi + {}_p D_{nm} \sin n\phi] \\ \times \sqrt{2(n+2m+1)} \left[\frac{J_{n+2m+1}(kaB)}{kab} \right] \quad (15-6)$$

In the previous equation, a is the radius of the geometrically projected circular aperture, J is the Bessel function, and

$$B = \sqrt{(\sin \theta \sin \phi - \sin \theta_B \sin \phi_B)^2 + (\sin \theta \cos \phi - \sin \theta_B \cos \phi_B)^2} \\ \phi = \tan^{-1} \left(\frac{\sin \theta \sin \phi - \sin \theta_B \sin \phi_B}{\sin \theta \cos \phi - \sin \theta_B \cos \phi_B} \right) \quad (15-7)$$

where (θ_B, ϕ_B) is the direction of the anticipated beam maximum (or its vicinity). It should be noted that when $B = 0$, i.e., in the boresight direction, only the first term of the series contributes. This first term is the Airy disk function, a typical far-field pattern of a uniform circular aperture. Another important feature of Eq. 15-6 is that the coefficients C and D do not depend on the observation points. These coefficients take the following form:

$$\left\{ \begin{matrix} {}_p C_{nm} \\ {}_p D_{nm} \end{matrix} \right\} = \frac{\epsilon_n}{2\pi} \int_0^{2\pi} \int_0^1 \mathbf{Q}_p \left\{ \begin{matrix} \cos n\phi' \\ \sin n\phi' \end{matrix} \right\} F_m^n(s') s' d\phi' ds' \quad (15-8)$$

where ϵ_n is the Neumann constant ($\epsilon_n = 1$ for $n = 1$, and $\epsilon_n = 2$ for otherwise), F_m^n is the modified Jacobi polynomial,¹⁸ and \mathbf{Q}_p is directly related to the physical optics induced current. The exact mathematical expression of \mathbf{Q}_p can be found in Rahmat-Samii and Galindo-Israel¹⁶ and Rahmat-Samii et al.¹⁸

Upon the observation that the far-field pattern is related to the Fourier transform of the aperture field, an efficient representation of the far field can be obtained by applying the sampling theorem, which allows you to express the far fields from a knowledge of fields at a limited number of sampling points,¹⁹ namely,

$$\mathbf{E} = \sum \sum \mathbf{E}_{nm} \frac{\sin(u - n\pi)}{u - n\pi} \frac{\sin(v - m\pi)}{v - m\pi} \quad (15-9)$$

where $u = ka' \sin \theta \cos \phi$ and $v = ka' \sin \theta \sin \phi$ (a' is the radius of an extended aperture¹⁹ in front of the reflector) and the \mathbf{E}_{nm} are the fields at the sampling points dictated by the Whittaker-Shannon theorem with spacing $\Delta u \leq \pi/a'$ and $\Delta v \leq \pi/a'$. This far-field representation is particularly useful when you are evaluating the fields at many observation points. A generalization of this procedure can also be obtained using nonuniform sampling techniques.²⁰

Geometrical Theory of Diffraction (GTD) Technique

Because the fundamentals of the geometrical theory of diffraction (GTD) are discussed in many books and articles, only its application to reflectors is summarized here. The foundation of GTD is based on the concepts of localization and ray picture satisfying Fermat's principle. These rays may be classified as the geometrical and edge-diffracted rays emanating from surface reflection and edge-diffracted points in accordance with Snell's law and Keller's theory.²¹⁻²³ For the reflector shown in Figure 15-3 the total scattered \mathbf{H} field may be expressed as

$$\mathbf{H}' = \theta^i \mathbf{H}^i + \sum_i \theta_i^r \mathbf{H}_i^r + \sum_j \mathbf{H}_j^d \quad (15-10)$$

where the superscripts i , r , and d denote the incident, reflected, and diffracted fields, respectively, and the subscripts i and j refer to the number of surface reflection and edge diffraction specular points, respectively, for a given feed and observation location. Additionally, θ^i and θ^r define the incident and reflected shadow indicators (i.e., $\theta = 0$ if the ray is blocked, and $\theta = 1$ if the ray path is unblocked).^{22,23} The \mathbf{E} field can be constructed in a straightforward manner using the fact that on each ray the \mathbf{E} and \mathbf{H} fields assume a local plane wave relationship, namely,

$$\mathbf{E} = Z \mathbf{H} \times \hat{\mathbf{r}}$$

where Z is the intrinsic impedance of the medium ($Z = 120\pi\Omega$ for the free space) and $\hat{\mathbf{r}}$ is the unit vector in the direction of each ray.

For a single feed with a well-defined phase center, we typically associate rays emanating from the phase center. For more distributed sources (arrays of feeds), you may have to associate many phase centers (one per feed element) and repeat the GTD construction for each of them. For a given feed position and specified observation point (this can be a point on the main reflector), you must first determine the GO reflection and edge-diffracted points (there can be more than one point for each type). There are various techniques for locating these points; however, all of them are based on Fermat's principle, which requires that the optical path be optimal (stationary). Fermat's principle may be invoked by requiring that the functional

$$d = d_{1(3)} + d_{2(4)} \quad (15-11)$$

as defined in Figure 15-3 be stationary with the constraint that Eq. 15-11 gives a solution(s) on the reflector surface and the edge boundary. Upon the determination of reflection and diffraction points from the solution of the preceding nonlinear equations, you can then apply the field construction of GTD to determine both the reflected and diffracted fields. The details of this construction may be found in Lee et al.,²² Rahmat-Samii et al.,²⁴ and other references.

FIGURE 15-3 Reflection and diffraction points for constructing the geometrical theory of diffraction (GTD) formulation along the reflected and diffracted rays

The reflected field transported along the reflected rays can be formulated as

$$\mathbf{H}'(P_2) = (DF)e^{-jk d_2} \{ \mathbf{H}^i(O^r) - 2[\mathbf{H}^i(O^r) \cdot \hat{\mathbf{n}}]\hat{\mathbf{n}} \} \quad (15-12)$$

which is given in terms of the incident field \mathbf{H}^i at the reflection point O^r , the unit surface normal $\hat{\mathbf{n}}$ at O^r , and a divergence factor (DF). This factor can be expressed as

$$DF = \frac{1}{\sqrt{1 + (d_2/R_1')}} \frac{1}{\sqrt{1 + (d_2/R_2')}} \quad (15-13)$$

where the square roots take positive real, negative imaginary, or zero values (so that DF is positive real, positive imaginary, or infinite). The terms R_1' and R_2' are the radii of principal curvature of the reflected wavefront passing through O^r . Their computation can be found in Lee et al.²²

For each diffraction point O^d in Figure 15-3, there is a contribution to the diffracted field \mathbf{H}^d in Eq. 15-10. The diffracted field can be expressed using the formulation in Lee et al.²²

$$\mathbf{H}^d(P_2) = \frac{1}{2\sqrt{2\pi d_4}} e^{-jk(d_4 + \pi/4)} \frac{1}{\sqrt{1 + (d_4/R_1)}} \frac{1}{\sin \beta} [\hat{\beta} D^h H_\beta^i + \hat{\alpha} D^s H_\alpha^i] \quad (15-14)$$

where

- R_1 = the radius of curvature of the diffracted wavefront passing through O^d
- β = the angle between the tangent to the edge and \mathbf{d}_4
- $\hat{\alpha}, \hat{\beta}$ = the unit vectors of the diffracted-ray coordinates
- D^h, D^s = the hard and soft diffraction coefficients
- H_α^i, H_β^i = the projections of the \mathbf{H}^i incident field on the ray coordinates at O^d

Note that Keller's standard diffraction coefficients diverge at the incident and reflected shadow boundaries, which can be corrected by applying a uniform diffraction coefficient. There are different uniform expressions for the diffraction coefficients, and the reader may refer to the literature²⁵⁻²⁸ for a detailed comparison. The most popular ones are the uniform theory of diffraction (UTD) and uniform asymptotic theory (UAT).

Aperture Field (AF) Technique

Another popular reflector analysis technique is based on the application of the aperture field, or AF, method. The mathematical construct of this technique requires that first a hypothetical planar aperture is erected in front of the reflector, and then the tangential fields are determined in this aperture using the GO and GTD constructions. It is customary to truncate the aperture to the reflector projected aperture size when dealing with well-focused pencil-beam antennas, and only the GO field construction is used. For cases where the feed is defocused or for fields at wide observation angles, however, you must use larger apertures to properly incorporate the contribution of the edge-diffracted fields. Alternatively you can use an aperture that caps the reflector's rim. Upon the determination of the tangential \mathbf{E} and \mathbf{H} fields in the aperture, the far fields can then be obtained using equivalence theorem.

There are typically three different representations for the construction of far fields that use either the aperture tangential \mathbf{E} or \mathbf{H} fields separately or a combination of them.

FIGURE 15-4 Reflector and aperture geometry and integration and observation parameters for constructing the aperture field (AF) formulation

These different representations are customarily referred to as different Kirchhoff approximations.⁴ One of the representations that use both the aperture tangential \mathbf{E} and \mathbf{H} fields and results in the far-field radiated tangential \mathbf{E} field can be formulated as

$$\mathbf{E} = \frac{-jk^2}{\omega\epsilon} g(r) \int_A \left\{ \hat{\mathbf{n}} \times \mathbf{H}^A - [(\hat{\mathbf{n}} \times \mathbf{H}^A) \cdot \hat{\mathbf{r}}] \hat{\mathbf{r}} - \frac{1}{Z} [(\hat{\mathbf{n}} \times \mathbf{E}^A) \times \hat{\mathbf{r}}] \right\} e^{jk\hat{\mathbf{r}} \cdot \mathbf{r}'} dA \quad (15-15)$$

where \mathbf{E}^A and \mathbf{H}^A are the \mathbf{E} and \mathbf{H} fields in the aperture with aperture size A and $\hat{\mathbf{n}}$ is the normal to this planar aperture, as shown in Figure 15-4. Variable $g(r)$ has already been defined in Eq. 15-2. For a planar aperture, Eq. 15-15 is a two-dimensional Fourier transform and can be evaluated in many different ways, one of which includes the use of the fast Fourier transform (FFT) algorithm.

Extension of Diffraction Analysis Techniques to Mesh, FSS, and Other Surfaces

There are many applications for which the reflector surface may not be simply a solid PEC surface. For example, mesh reflectors are used in large unfurlable antennas, FSS (frequency selective surfaces) are used as subreflectors for frequency separation of feeds, the reflector surface may be affected by snow, etc. In all these cases, you can modify the PO integral and incorporate the effects of these surfaces.^{29–33}

Near, Fresnel, and Far Fields of a Reflector Antenna

Before closing this section it is worthwhile to present data on the near, Fresnel, and far fields of a typical parabolic reflector antenna. This is useful for developing an insight into the evolution of radiated fields away from the reflector. For the sake of simplicity, only the uniform aperture distribution is considered, and its radiated fields at many different distances from the aperture are constructed by numerically evaluating Eq. 15-1. Results are shown in Figure 15-5, where you can readily observe how the far-field pattern is formed at distance $R > 2D^2/\lambda$. For very low sidelobe reflectors, distances much greater than $2D^2/\lambda$ are required to obtain an accurate description of inner sidelobes. These results are constructed for a symmetric parabolic reflector antenna with diameter of 100 wavelengths and $F/D = 0.4$ with almost no taper illumination.

FIGURE 15-5 Radiated field pattern of a reflector antenna as a function of distance R

15.3 CONVENTIONAL REFLECTOR ANTENNAS

The reflector antennas treated in this chapter are those that have been used for decades. The very-high-gain reflectors used in earth stations, which have a more sophisticated design, are treated in the later sections of this chapter. As mentioned earlier, the conventional reflector designs are (1) planar, (2) parabolic-arc, (3) double-curvature, (4) paraboloid, and (5) shielded reflectors. In addition, passive reflectors used in communications and radar are described. More sophisticated large reflectors will be discussed at the end of this chapter.

Corner Reflector³⁴

The corner-reflector antenna is made up of two plane reflector panels and a dipole element (see Figure 15-6). This antenna is useful in obtaining gains of the order of 12 dBi. Higher gains can be obtained by using large reflectors and larger spacing of the dipole to the panel intersection. The gain also depends upon the corner angle. Figure 15-7 shows the gain as a function of dipole spacing for four values of corner angle. Figures 15-8 through 15-11 show the radiation patterns for E and H planes. One of the angles is 180° , and the data therefore include the planar reflector.

FIGURE 15-6 Corner-reflector antenna and coordinate system

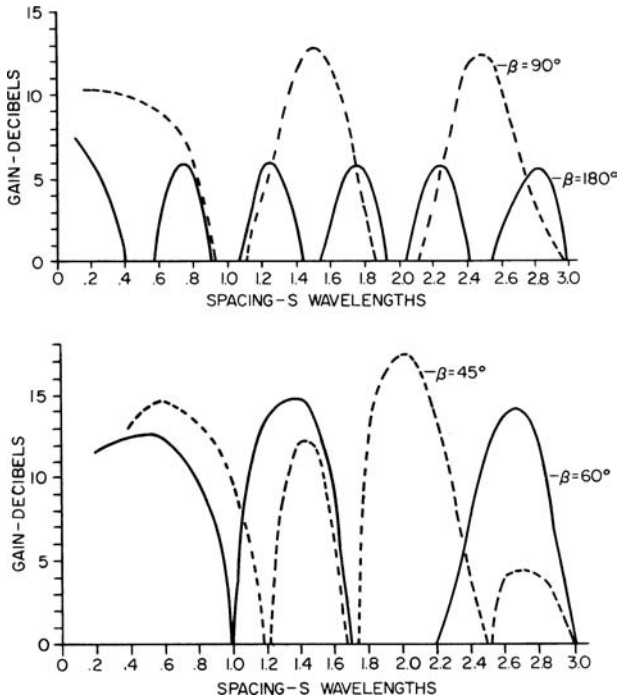

FIGURE 15-7 Gain of corner reflectors

FIGURE 15-8 Patterns of 60° corner, S_λ variable

FIGURE 15-9 Patterns of 90° corner, S_λ variable

The size of reflector panels is a compromise between gain and antenna wind load. The wind load is reduced by replacing the panels by parallel rod reflectors with spacing of $\lambda/10$. The rod length should be 0.6λ . The size of the reflector panels must be increased as the dipole spacing is increased. A spacing of $\lambda/3$ requires a panel length of 0.6λ , a spacing of $\lambda/2$ requires λ , etc. The impedance of the corner reflector depends upon the spacing and upon the dipole impedance. Spacing of less than $\lambda/3$ for the 90° corner is not recommended. Larger spacing has less effect on impedance.

FIGURE 15-10 Patterns of 120° corner, S_λ variable

FIGURE 15-11 Patterns of flat-sheet, S_λ variable

An increase in the corner-reflector gain³⁵ is obtained by adding a third panel, which serves as a ground plane for a 0.75λ monopole feed. The long monopole gives a peak signal above the ground plane (about 45°). The panel lengths are 2λ , and the monopole spacing is about one wavelength. As in the conventional corner reflector, the gain depends upon corner angle and spacing: 90° and 0.9λ give 17 dBi, 60° and 1.2λ give 19 dBi, and 45° and 1.6λ give 21 dBi.

An increase in corner-reflector bandwidth³⁶ can be achieved with a broadband dipole feed. An open-sleeve dipole with the center section of coaxial line in the sleeve replaced by slab line gave almost an octave bandwidth with a voltage-standing-wave-ratio (VSWR) of 2.5:1. The gain was 11.5 ± 1 dBi. The match was achieved by a cut-and-try procedure.

Reflectors with Parabolic Arc

The parabolic arc can be used as a generating curve for a number of useful reflector surfaces. When moved so that the focal point travels along a straight line, the curve generates a parabolic cylinder. With a limited motion along this line, the reflector for a pillbox is generated. When the focal point is moved along a circle enclosing the arc, an hourglass surface is generated, and for a circle that does not enclose the arc a parabolic torus is generated. Figure 15-12 shows the basic parameters of these surfaces.

Parabolic Cylinder

The elements of the cylinder are all perpendicular to the plane of the parabolic arc. Because this is a singly curved surface, problems of construction and maintaining tolerances are somewhat easier than those encountered in the case of the paraboloid. The cylinder can be constructed of tubes or slats that are straight-line elements of the surface, or it can use identical parabolic arcs formed of tubes or slats positioned so that the planes of the parabolic arcs are perpendicular to the elements of the cylinder.

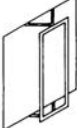

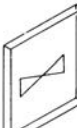

REFLECTOR		DIMENSIONS (WAVELENGTHS)	BANDWIDTH (%)	DIRECTIVE GAIN (dBi)
MICROSTRIP		0.5×0.5 $t = 0.05$	1%	6
SKELETON SLOT		0.5×0.5 $t = 0.25$	80%	9
PLANETENNA		1.0×1.0 $t = 0.1$	30%	11
SHORT BACKFIRE		$D = 2$ $t = 0.5$	10%	15
GRID ARRAY		$D = 5$ $t = 0.05$	15%	22

FIGURE 15-12 Various reflector configurations with parabolic curves

The widest use of the cylinder is with a line-source feed, which may be formed in a number of ways. The line-source aperture is made to coincide with the focal line of the cylinder (the line made by joining the focal points of all arcs). The aperture of the line source can contain energy in phase along the length or have a linear-phase variation along the length. The first produces a cylindrical wavefront, while the linear-phase variation produces a conical wavefront. The cylindrical wave is focused into a plane wave in the direction of the axis of a parabolic arc. The conical wavefront produces a plane wave tilted from the parabolic axis by an angle equal to the half angle of the cone.

The illumination problems of a line-source feed with the cylinder are related to those of the paraboloid. The decrease in energy in the cylindrical or conical wave is proportional to distance rather than to the square of the distance. The sidelobes present a problem in the parabolic cylinder since the relative gain between the line source and the final antenna system is not sufficient to suppress the sidelobes of the source. Care must be given to the design of the aperture of the line source, particularly in control of the *E*-plane sidelobes.

The feed-blocking problem for a line source and parabolic cylinder is serious since the line source presents a large blockage. For this reason, it is usually desirable to use an offset reflector in which the line-source feed structure is removed from the path of the reflected radiation.

The parabolic cylinder can be fed by a point-source feed horn. The horn illumination function is defined by energy that falls off with the square of distance. The reflected wavefront will be a cylinder with elements perpendicular to the elements of the parabolic cylinder. In one plane the point source is focused, and in the other plane the cylinder reproduces the pattern of the feed horn. The result can be a narrow beam in azimuth and a broad-coverage beam in elevation. The best work on such an antenna used a cylinder with its straight-line elements tilted from vertical. Close-in sidelobes were controlled, and the largest sidelobes (of the order of -28 dB) were removed from the main-beam region. This reflector operated at 9.3 GHz and measured 5 ft by 1 ft (1.5 m by 0.3 m), with a focal length of 1.5 ft (4.5 m). The tilt of the reflector was 12° .

Since the horn and cylinder will give a cylindrical wave and the parabolic cylinder focuses the cylindrical wave, a second reflector can be used. Use of a point-source feed and two parabolic cylinders gives a final wavefront identical to that of a paraboloid. If the equation of the first cylinder is $y^2 = 4fx$, with f the focal length, the second cylindrical surface is given by $(x+f)^2 = 4f(z+f)$, and the final rays are all parallel to the z axis. The plane curves of intersection for the cylinders before development are given in Spencer et al.³⁷

The parabolic cylinder can also be used as the reflector in the pillbox, or cheese, antenna. The pillbox is formed by two parallel planes that cut through a parabolic cylinder perpendicular to the cylinder elements. Typically the focal line of the cylinder is positioned in the center of the aperture formed by the open ends of the parallel plates. When a feed is placed at the focal line, it blocks a significant portion of the open region. The blockage causes large sidelobes in the pattern of the pillbox. The feed backlobes are significant, and a portion of the feed's radiation is reflected back into itself to produce a standing wave. An improvement in performance is obtained when a half pillbox is used in the same fashion as the offset parabolic cylinder. The arc of the parabola extends from the vertex to the 90° point. The feed horn is pointed at the 45° point, and although the illumination is asymmetrical, good sidelobes are obtained. The maximum sidelobe of -26 dB was from the spillover past the 90° point of the parabolic arc. A recent spaceborne concept was designed and tested in Rahmat-Samii et al.³⁸

Hourglass Reflector³⁹

The hourglass reflector is generated by rotating a parabolic arc (symmetrical or offset) about a vertical axis that is on the convex side of the arc. The feed system for the hourglass reflector is a circular array. The hourglass serves to give increased gain in the vertical plane. The circular array has the characteristics of the Wullenweber system,⁴⁰ which provides scanning beams, fixed beams, and beams from a hybrid matrix system. The sidelobes in the elevation plane are controlled by controlling the elevation pattern of the array elements. In the horizontal plane the sidelobes are controlled by tapering the energy in the array elements.

Parabolic Torus⁴¹

This reflector is formed by rotating the parabolic arc about a vertical axis positioned on the concave side of the arc. It can be formed by a symmetrical arc or by the more widely used offset arc. This reflector is fed by multiple feed horns, each of which uses portions of the reflector surface used by adjacent horns. With multiple usage of the surface, a relatively compact structure can be obtained. The final surfaces with a parabolic arc are the elpar and hypar surfaces with an ellipse and a hyperboloid in the second principal plane. These reflectors are discussed in the next subsection. A recent spaceborne concept was suggested in Hoferer and Rahmat-Samii⁴² and Njoku et al.⁴³

15.4 OFFSET (SYMMETRIC) PARABOLOIDAL REFLECTORS

Since offset (symmetric) paraboloidal reflector antennas are still one of the most popular reflector antenna configurations, in this section the radiation characteristics of offset (symmetric) paraboloidal reflector antennas illuminated by a single-feed element (fixed-phase center) are presented with ample parametric studies. As is typical in any reflector design, there are too many almost-independent parameters that may be varied to achieve a particular design goal. For instance, to design an offset parabolic reflector, you must study the effects of such parameters as offset angles, illumination tapers, F/D ratios, locations and orientations of the feed, polarizations, etc., on such far-field pattern characteristics as scan loss, beamwidth, sidelobe level, cross-polarization level, efficiency, and so on. Obviously it is not possible to perform a comprehensive study of all these parameters; rather, attempts are made to present the most important reflector characteristics based on a few key parameters. The results of this section can therefore be used as a guideline for an initial design, which can then be refined by using computer programs and measured data.

Geometrical Parameters

The geometry of an offset parabolic reflector with focal length F , diameter D , and offset height H is shown in Figure 15-13. There are also other parameters used to characterize offset parabolic reflectors, which are defined next:

F = focal length

D = reflector diameter (diameter of the circular projected aperture)

H = offset height ($H = -D/2$ for symmetric reflectors)

d = offset height of the circular projected aperture center

$$= D/2 + H$$

ψ_U = angle subtended to the upper tip

$$= 2 \tan^{-1}[(D + H)/2F]$$

ψ_C = angle subtended to the center of the projected aperture

$$= 2 \tan^{-1}[(D/2 + H)/2F]$$

ψ_L = angle subtended to the lower tip

$$= 2 \tan^{-1}[H/2F]$$

ψ_B = angle subtended in the bisect direction

$$= (\psi_U + \psi_L)/2$$

ψ_S = half-angle subtended to the upper and lower tips

$$= (\psi_U - \psi_L)/2$$

ψ_{SC} = half-angle subtended to the right and left sides

$$= \sin^{-1} \left(\frac{D}{2} / \sqrt{\left(H + \frac{D}{2}\right)^2 + \left(\frac{D}{2}\right)^2 + \left[\frac{(D/2)^2 + (H + D/2)^2}{4F} - F\right]^2} \right)$$

D_p = parent parabola diameter

$$= 2(D + H) \text{ for } H \geq -D/2$$

In some cases F , ψ_B , and ψ_S are given, and from them D and H may be constructed. This can be done by using the following expressions:

$$D = 4F \sin \psi_S / (\cos \psi_B + \cos \psi_S)$$

$$H = 2F(\sin \psi_B - \sin \psi_S) / (\cos \psi_B + \cos \psi_S) \quad (15-16)$$

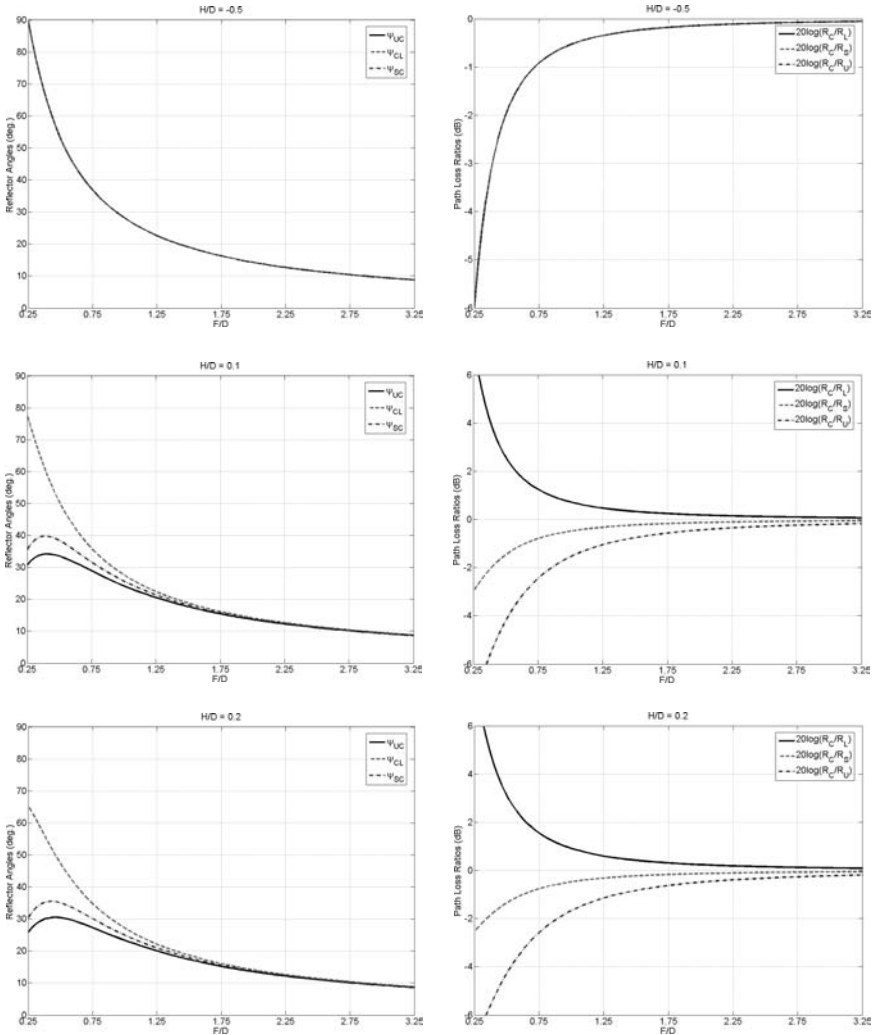

FIGURE 15-15 Reflector angles and path loss ratios, as defined in Figure 15-13, as a function of F/D : (a) for $H/D = -0.5$ (symmetric reflector case); (b) for $H/D = 0.1$ and (c) For $H/D = 0.2$

useful models, are used. For an idealized feed with a fixed phase center, its radiation pattern may be described as

$$\mathbf{E}(\mathbf{r}) = A_0 \begin{cases} \hat{\theta} C_E(\theta) \cos \phi - \hat{\phi} C_H(\theta) \sin \phi \\ \hat{\phi} C_E(\theta) \sin \phi + \hat{\theta} C_H(\theta) \cos \phi \end{cases} \frac{e^{-jkr}}{r}, \quad \begin{cases} \text{for } \hat{x} \text{ polarized} \\ \text{for } \hat{y} \text{ polarized} \end{cases} \quad (15-17)$$

where A_0 is a complex constant and

$$\begin{aligned} C_E(\theta) &= (\cos\theta)^{q_E} = E\text{-plane pattern} \\ C_H(\theta) &= (\cos\theta)^{q_H} = H\text{-plane pattern} \end{aligned} \quad (15-18)$$

for $0 \leq \theta \leq \pi/2$ and zero otherwise. There are other versions of this idealized feed pattern with a half angle representation that covers the entire angular range.

The shape of the pattern is controlled by q_E and q_H , which are determined by matching Eq. 15-18 to the given feed pattern. A proper superposition of the x and y polarized components in Eq. 15-17 also generates a circularly polarized field, namely,

$$\mathbf{E}(\mathbf{r}) = A_0 e^{j\tau\phi} [\hat{\theta} C_E(\theta) + \hat{\phi} j\tau C_H(\theta)] \frac{e^{-jkr}}{r} \quad (15-19)$$

where $\tau = +1$ for left-handed circular polarization, and $\tau = -1$ for right-handed circular polarization. Note that Eq. 15-19 represents a perfect circular polarized wave only in the main beam direction ($\theta = 0$). Away from this direction it is generally elliptically polarized unless $q_E = q_H$.

An attractive feature of Eq. 15-17 is that the directivity is derived in closed form:

$$D(\theta = 0) = \frac{2(2q_E + 1)(2q_H + 1)}{q_E + q_H + 1} \quad (15-20)$$

which consequently allows computation of the directivity of the reflector illuminated by this feed.⁴⁴ It must be noted that the back radiation of the feed pattern is ignored in deriving Eq. 15-20.

Edge and Feed Tapers

A widely employed parameter to characterize the effects of the feed element pattern on the far-field pattern of the reflector is the *edge taper*. In a broad sense this signifies the ratio of the field intensity at the reflector edge to the intensity at its center in decibels. Although this definition is unambiguous when it is applied to symmetric reflectors, it can become ambiguous for offset reflectors. For this reason another definition, referred to as *feed taper*, is defined.

Referring to Figure 15-13, the feed taper FT_U in the upper-tip direction is defined as

$$FT_U = 20 \log \left[\frac{C(\psi_U - \psi_C)}{C(0^\circ)} \right] \quad (15-21)$$

where 0° refers to the central direction (i.e., OC in Figure 15-13) and C denotes the feed pattern as defined in Eq. 15-18. Similar definitions for FT_L and FT_S can also be given at the lower and side angles by using ψ_C , ψ_L , and ψ_S , respectively. The edge taper ET_U at the upper tip may now be expressed as

$$ET_U = FT_U + 20 \log(R_C / R_U) \quad (15-22)$$

where R_C and R_U are the path lengths from the feed to the center and the upper tip of the reflector, respectively. The second term in Eq. 15-22 is also called the *path loss* term. Similar definitions can also be given for ET_L and ET_S . Note that for symmetric reflectors,

ET and FT only need to be defined at one edge (tip). For different values of F/D and F/D the path loss curves are shown in Figures 15-15a through 15-15c. It is worthwhile to add that for most cases of interest, ET_U , ET_L , and ET_S have nearly equal values. Since ET directly controls the reflector's aperture amplitude taper, it has a more dominant effect on the far-field pattern than FT does. It is not only the taper level that controls the reflector pattern but also the overall shape of the illumination distribution. In particular, the slopes of the illumination pattern at the reflector's edge can affect the sidelobe levels. The results of this section are primarily based on the $\cos^q(\theta)$ type illumination patterns.

Reflector Pattern Characteristics for On-Focus Feeds

Reflector pattern characteristics are discussed for beams generated by feeds located on the focus. Results are shown for beamwidths, sidelobe levels, first-null positions, cross-polarization levels, directivity efficiency, etc., as functions of the edge taper ET (or feed taper FT) and the reflector geometries. To simplify the presentation and limit the number of graphs, cases are considered in which the path losses are small (less than 0.5 dB) and, therefore, no substantial differences can be observed for path losses at the different tips of the reflector. For these cases, $\psi_{UC} \approx \psi_{CL} \approx \psi_{SC} \approx \psi_S$ and $FT \approx ET$. The reader should attempt to properly interpret the results when the path losses are substantial. This effect is clearly demonstrated in Figure 15-16, which displays far-field patterns for symmetric reflectors ($H/D = -0.5$) for the cases of $F/D = 0.4$ and $F/D = 2.0$, with an edge taper of $ET = -10$ dB. From Figure 15-15a it is concluded that the path losses are -2.86 dB and -0.13 dB for F/D s of 0.4 and 2.0, respectively. Nevertheless, the patterns are very similar, which indicates that $ET = -10$ dB is the controlling factor. Note that for these values of F/D the feed taper FT takes the values of -7.14 dB and -9.87 dB, respectively. In the latter case, $ET \approx FT$. Similar results are shown in Figure 15-17, where the feed taper FT is kept constant at -10 dB. The patterns for cases in which $F/D = 0.4$ and 2.0 show differences of up to 2.8 dB at the first sidelobe level, which is obviously a manifestation of the effects of the path loss differences.

For offset parabolic reflectors the far-field patterns in different cuts are, in general, different even when the feed has a symmetric pattern. Also, the pattern can be slightly asymmetric in the plane of offset depending on the F/D ratio (see Figure 15-18).⁴⁵ However, for the results shown here, F/D is large in order to reduce the path loss effects and asymmetry

FIGURE 15-16 Far-field patterns of a symmetric reflector antenna with an edge taper illumination of $ET = -10$ dB and different path losses (different F/D values)

FIGURE 15-17 Far-field patterns of a symmetric reflector antenna with a feed taper illumination of $FT = -10$ dB and different path losses (different F/D values)

of the pattern. Figure 15-19 shows the half-beamwidth, first and second null positions, and first sidelobe positions as functions of the edge taper ET . It is worthwhile to mention that for edge tapers beyond -20 dB the pattern characteristics depend heavily on the actual feed pattern description, and results shown here are for $\cos^q(\theta)$ feed patterns. Also shown in Figure 15-20 are the first sidelobe levels and spillover and taper efficiencies as functions of edge tapers. From Figure 15-20 it is readily observed that the resulting efficiency $\eta = \eta_s \eta_t$ is maximized for edge tapers about -11 dB with a value of 81 percent. Some representative far-field patterns are shown in Figure 15-21 for different edge tapers. Again, it is obvious that for edge tapers in the neighborhood of $ET = -20$ dB, the first sidelobe starts to merge with the main beam, which results in a widened beam. For this level of edge taper the exact distribution of the feed pattern can have a significant effect on the pattern characteristics.

Another important reflector parameter is the level of generated cross-polarized field. This topic has been addressed in Love,³ Chu and Turrin,⁴⁶ and Ludwig⁴⁷ for both symmetric and

FIGURE 15-18 Patterns of an offset reflector with $H/D = 0.5$ ($F/D_p = 0.25$) illuminated by a symmetric feed with a feed taper of $FT = -10$ dB

FIGURE 15-21 Reflector far-field patterns for different edge tapers

FIGURE 15-22 Cross-polarized field (normalized with respect to the main beam) of a symmetric reflector ($F/D = 0.3$) illuminated by a linearly polarized feed with unbalanced E - and H -patterns.

offset reflectors. Here, some representative cases are presented. There are many different cases that can be studied. Commonly the unbalanced feed refers to a feed with different E - and H -plane patterns. For the symmetric reflector the mechanism of generation of the cross-polarized field is related to the aperture field decomposition, and some typical patterns are given in Figure 15-22. Note that for a symmetric parabolic reflector illuminated by a linearly polarized feed, the maximum of cross-polarized fields occurs in the plane $\varphi = 45^\circ$. As the feed becomes more balanced, the level of the cross-polarized field decreases substantially, as demonstrated by the results in Figure 15-22. It is worth mentioning that these results are dependent on the F/D ratio and the edge taper.

Next, the cross-polarization characteristics of offset parabolic reflectors are considered. In contrast to symmetric reflectors, which have very low levels of cross-polarized fields for balanced and linearly polarized feeds, offset parabolic reflectors can have a high level of cross polarization. Even for balanced feeds located at the focal point, levels of cross-polarized fields can be high, depending on the tilt angle of the feed axis with respect to the reflector axis for linearly polarized feeds. For example, Figure 15-23 shows the generation of cross-polarized fields for various feed-axis tilt angles for a fixed offset reflector configuration. In this example the feed pattern is chosen to be isotropic in order to show clearly the generation of the cross-polarized fields. It should be mentioned that for offset parabolic reflectors the cross-polarized field is predominantly observed in the plane $\varphi = 90^\circ$ (normal to the plane of the offset). Clearly, in practice, to reduce spillover the feed axis is always tilted toward the center of the reflector; hence a high level of cross-polarized field should be expected. The levels of cross-polarized fields for different values of bisect angle ψ_B and the half-angle ψ_s (see Figure 15-23) can be generated.⁴⁶

When symmetric or offset parabolic reflectors are illuminated with balanced circularly polarized feeds, very low levels of cross-polarized fields result. For offset parabolic reflectors illuminated by circularly polarized feeds, however, an additional feature is observed, which is referred to as the *beam squint*. This means that the beam peak is shifted from the axis on the plane normal to the plane of offset. The amount of squint depends on the tilt angle of the feed axis and the reflector geometry. It can be shown that the following expression is a good approximation:

$$\sin \theta_s = \mp \frac{\sin \psi_B}{4\pi(F/\lambda)} \quad (15-23)$$

FIGURE 15-23 Cross-polarized fields in the plane $\phi = 90^\circ$ (normal to the offset plane) for an offset parabolic reflector for various feed-axis tilt angles ψ and illuminated by a balanced linearly polarized feed

where \mp signs are for right and left circularly polarized cases and θ_s is the amount of squint. The amount of squint obtained from experimental data and diffraction analysis⁴⁶ agrees well with the approximate formula. Additional results are shown in Figure 15-24,⁴⁶ where again ψ_B is used to characterize the reflector.

Reflector Pattern Characteristics for Off-Focus Feeds

In many applications, such as the design of multiple and contour beam reflectors, it becomes necessary to illuminate the reflector with feeds positioned away from the reflector focal point. This feed displacement introduces phase aberration, which results in pattern distortion in terms of gain loss, sidelobe degradations, etc. In this subsection some of the key distortion characteristics of reflectors are presented for both the symmetric and offset parabolic reflectors and for both the axial and lateral feed defocusing.

FIGURE 15-24 Squinted far-field patterns in the plane $\phi = 90^\circ$ of an offset parabolic reflector illuminated by right and left circularly polarized feed located at its focal point

Axial Displacements For the symmetric reflector the results of feed axial defocusing for gain loss and patterns are shown in Figures 15-25 through 15-27. It is assumed that the feed provides a -10-dB edge taper when it is located at the focal point. Results are demonstrated for feed displacements toward and away from the reflector. A small asymmetry can be observed. These results are dependent on the edge taper as discussed in Ingerson and Rusch.⁴⁸ Furthermore, for the cases where $\delta \ll F$ and the feed is an infinitesimal dipole with moment \mathbf{p} polarized in the $\hat{\mathbf{y}}$ direction, you can obtain the following approximate expression⁴⁸ for the field on axis:

FIGURE 15-25 Relative on-axis field as a function of axial feed displacement

$$\mathbf{E}(R,0,0) = -\frac{jk^2 p}{4\pi\epsilon} (2kF) \hat{\mathbf{y}} \frac{\exp(-jkR)}{R} \frac{1}{(4F/D)^2 + 1} \exp\left[-jk\delta \frac{(4F/D)^2}{(4F/D)^2 + 1}\right] \frac{\sin \xi}{\xi} \quad (15-24)$$

$$\xi = \frac{2\pi(\delta/\lambda)}{(4F/D)^2 + 1} \quad (15-25)$$

The dominant effect of the axial defocusing is the generation of the quadratic phase error across the reflector aperture. The axial field (see Eq. 15-24) becomes virtually zero for values of $\xi = \pm\pi, \pm2\pi, \pm3\pi$, etc., which results in

$$\frac{\delta}{\lambda} = \pm \frac{n}{2} [(4F/D)^2 + 1], \quad n = 1, 2, 3, \dots \quad (15-26)$$

For these values the beam widens considerably and may also be bifurcated (see Figures 15-26 and 15-27). You may have noticed a resemblance between these patterns and those resultant from the field of an aperture in the Fresnel zone.

FIGURE 15-26 Reflector far-field patterns for $\varphi = 0^\circ$ as a function of axial feed displacement away from the reflector

FIGURE 15-27 Reflector far-field patterns for $\phi = 0^\circ$ as a function of axial feed displacement toward the reflector

Lateral Displacements For a parabolic reflector, lateral feed displacements result in scanned beams. It is well known that these reflectors have limited scan capability that strongly depends on F/D and F/D_p ratios for symmetric reflectors. An important parameter in dealing with scanned beams is the beam deviation factor (BDF), which is defined as

$$BDF = \frac{\theta_B}{\theta_F} \quad (15-27)$$

where θ_B and θ_F are the beam scan angle and feed tilt angle, respectively, as shown in Figure 15-28. The BDF has a strong dependence on F/D and weakly depends on the edge taper and δ/F (δ is the lateral feed displacement). A good approximation for BDF is⁴⁹

$$BDF = \frac{\sin^{-1}(\delta/F)\{[1 + k(D/4F)^2]/[1 + (D/4F)^2]\}}{\tan^{-1}(\delta/F)} \quad (15-28)$$

FIGURE 15-28 Beam deviation factor ($BDF = \theta_B/\theta_F$) as a function of the F/D ratio for symmetric reflectors ($ET = -10$ dB)

FIGURE 15-29 Radiation patterns for focused and laterally defocused feeds

where $0 < k < 1$ and $k = 0.36$ provide very accurate results when the BDF is compared with experimental and diffraction analysis data. For small δ/F , Eq. 15-28 may be simplified to give

$$BDF_0 = \frac{1 + k(D/4F)^2}{1 + (D/4F)^2} \quad (15-29)$$

which is independent of δ/F . Figure 15-28 shows the BDF as a function of F/D and for $k = 0.36$. For large feed displacements you may have to resort to diffraction analysis results in order to obtain more accurate values for the BDF.

Due to the phase aberration introduced by defocused feeds, the far-field pattern can be substantially degraded, as shown in Figure 15-29. This degradation depends very strongly on the F/D ratio and the angle of scan in terms of number of beamwidths scanned (bmws). Some approximate formulas are available for predicting the peak gain loss as a function of beamwidths scanned.⁵⁰ In many applications, however, the knowledge of peak gain loss is not sufficient, and you must know the overall degradation effects on the far-field pattern. For this reason many selective but representative cases are given here to provide a clear picture of the pattern degradation. First, an $F/D = 0.4$ symmetric parabolic reflector illuminated by a $\cos^q(\theta)$ type feed with $ET = -10$ dB is considered. Far-field patterns for different numbers of beamwidths scanned are shown in Figure 15-30. It is important to note that the patterns are plotted versus the universal parameter $ka \sin \theta_p = \pi(D/\lambda) \sin \theta_p$, in which θ_p is the angle measured from the axis passing through the peak of the beam that is directed in the $\theta_b = BDF \tan^{-1}(\delta/F)$ direction. The peak values of these patterns are normalized with respect to the peak value of the nonscanned beam. Note that for large scan angles, $BDF = 0.82$ (for $F/D = 0.4$) does not predict the location of the beam maximum accurately. Furthermore, the feed axis is kept parallel to the reflector axis and has not been tilted toward the reflector center. This condition is more practical when feeds are used in planar array in contour and multiple beam applications. For directive feeds with large displacements, however, it may be necessary to tilt the feed toward the reflector center in order to reduce the amount of spillover. In this case the feeds may be arrayed on the spherical surface rather than the planar surface. Figure 15-30 clearly demonstrates how rapidly the reflector pattern can degrade for scan angles beyond two beamwidths scanned when $F/D = 0.4$.

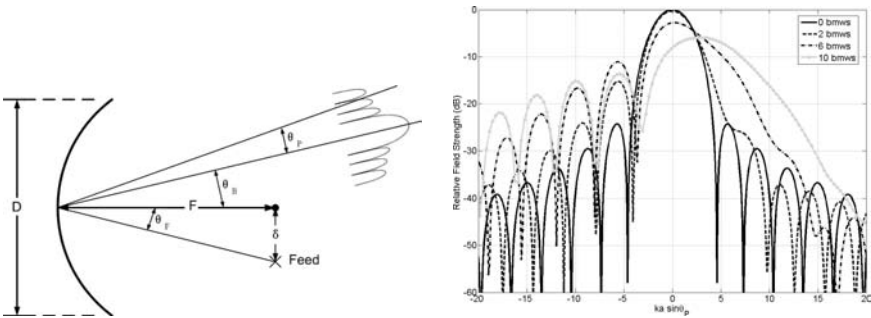

FIGURE 15-30 Symmetric reflector far-field patterns for $\phi = 0^\circ$ plane as a function of lateral feed displacement in terms of the number of beamwidths scanned ($F/D = 0.4$, $ET = -10$ dB, $BDF = 0.82$): (a) reflector parameters and (b) far-field patterns

One simple way to improve this very limited scan capability is to increase the F/D ratio. Figure 15-31 shows the far-field patterns for $F/D = 1.0$ as a function of beamwidths scanned. Note that for this value of F/D , beams with much larger scan angles can be generated with adequate characteristics. The prime drawbacks of employing large F/D values are the larger structural size and the need for more directive feeds to provide the required edge taper. Finally, Figure 15-32 shows the gain loss curves for different values of F/D as a function of the beamwidths scanned (bmws). Although most of the results are shown for the case of $ET = -10$ dB, similar observations can be made for other edge tapers. For example, Figure 15-33 shows the results of experimental data.⁵¹ Excellent agreement has been observed as far as the effects of the feed displacements are concerned. There are, however, differences in the third sidelobe levels due to the fact that the experimental feed patterns are not exactly modeled by the $\cos^q(\theta)$ type pattern.

FIGURE 15-31 Symmetric reflector far-field patterns for $\phi = 0^\circ$ plane as a function of lateral feed displacement in terms of the number of beamwidths scanned ($F/D = 1.0$, $ET = -10$ dB, $BDF = 0.966$)

FIGURE 15-32 Peak gain loss of symmetric parabolic reflectors as a function of beamwidths scanned for different F/D ratios

The previously mentioned results for symmetric reflectors only demonstrate the scan characteristics while ignoring the blockage effects, which could become very severe if large feed arrays are used to illuminate reflectors for multiple and contour beam applications. To overcome these blockage effects, the designers of satellite communications systems frequently employ offset reflectors that have scan characteristics as discussed here. For offset reflectors the beam deviation factor is computed as shown in Figure 15-34. Many studies have shown that the F/D_p ratio characterizes the offset reflector patterns better than the F/D ratio. Far-field patterns as a function of the number of beamwidths scanned are shown in Figure 15-35 for $F/D_p = 0.4$ and $ET = -10$ dB. For this case $F/D = 0.96$ ($F = 96\lambda$, $D = 100\lambda$, $H/D = 0.2$), which is almost two and a half times larger than F/D_p . Notice the similarity between these patterns and those of the symmetric reflector with $F/D = 0.4$ (Figure 15-30b). Similar results are also shown for an offset reflector with $F/D_p = 1.0$ and $F/D = 2.4$. Figure 15-36 shows the patterns for the cases in which the feed

FIGURE 15-33 Measured secondary patterns as a function of lateral primary feed displacement for a symmetric parabolic reflector⁵¹

FIGURE 15-34 Beam deviation factor versus F/D for different offset angles ψ_C

direction is kept fixed as the feed is displaced in the plane orthogonal to the line joining the focal point with the reflector center. For this large value of F/D_p , the feed is very directive in order to provide the -10 -dB edge taper and, therefore, for large scans the reflector would be very poorly illuminated. Results for the cases in which feed is tilted toward the reflector center while it is displaced in the focal plane are shown in Figure 15-37. Notice that a marked improvement can be observed in the patterns. Finally, the peak gain losses as a function of beamwidths scanned and for different values of F/D_p are plotted in Figure 15-38. It is worthwhile to mention that there are a considerable number of ongoing attempts to improve the scan performance of single-reflector antennas by employing the concept of conjugate matched focal-plane feed arrays. This approach may also be utilized to overcome the deterministic reflector surface distortions.

FIGURE 15-35 Offset reflector far-field patterns as a function of lateral feed displacement in terms of the number of beamwidths scanned ($F/D_p = 0.4$, $F/D = 0.96$, $ET = -10$ dB, $BDF = 0.983$, $\varphi = 0^\circ$)

15.5 REFLECTORS OTHER THAN PLANE OR PARABOLIC

Some key feature of popular and non-parabolic reflector antennas are discussed in this section. Attempts have been made to provide design curves and an overview of their radiation characteristics.

General Surface

There are a number of useful surfaces in addition to the plane and the surfaces with a parabolic arc. The coordinates of these surfaces are determined by the required phase and amplitude at points on the reflected wavefront. The phase is associated with the length of the incident and reflected ray paths,⁵² and the amplitudes depend upon the density of the rays.⁵³ The most widespread use of general surfaces has been in shaped beams and Cassegrain antennas, but other useful surfaces are included here.

Sphere

The first surface considered is the sphere (see Figure 15-39), which was shown in Kelleher⁵² to have the phase error $2(1 - a^2)^{1/2} + 2(da^2 - 1)$, where d is the distance from the sphere center to the feed and a is the distance from the centerline to the spherical surface. The sphere has unit radius. A practical sphere is limited in extent. If an attempt is made to scan it to one side, the phase errors do not remain the same, but increase as the beam is moved off axis. That is, the value of r in the expression for phase error must increase on one side and decrease on the other. Consider a plane through the sphere containing the axis. The phase-error expression can be plotted in Figure 15-40 for a number of values of the feed position d . The reflector edges move across the phase-error curves as the feed horn is

FIGURE 15-39 Reflectors other than parabolic

FIGURE 15-40 Phase error in a spherical reflector

moved off axis. The error will decrease slightly on one side and increase very rapidly on the other side. A careful analysis of the error will show that it has a strong cubic term (coma), just as the paraboloid has a strong cubic term. The sphere and the paraboloid have similar off-axis characteristics.

If the spherical reflector can have an efficiency on the order of 10 percent, it will give patterns that do not change with the beam moved off axis.⁵⁴ In this instance, the sphere is fed from a large feed horn that confines its radiation to a small portion of the surface. The reflector edges that were the problem in the normal sphere are then eliminated. In effect, this solution uses a very-long-length system in which the paraboloid and the sphere become very much alike.

The design of the sphere is based upon the phase-error formula. The error curve is used out to the point at which the phase error is zero. An argument can be made that some phase error beyond this point can be accepted. A tapered illumination from the feed will minimize these errors. In practical design, however, the phase error increases so fast that only a marginal improvement is achieved by considering the feed illumination. Some fine-tuning can be done with illumination, but the basic design depends upon the simple use of the two points on the phase-error curves, namely, the maximum value and the edge (zero) value that defines the maximum value of the aperture radius r . A simple ratio, namely, maximum phase error divided by r , is used. Let the phase error be $\lambda/16$ and the radius be 10λ (aperture diameter of 20λ). The ratio is 160:1. The design consists of selecting a specific curve using the parameter d that gives a ratio of 160:1. Note that the y coordinate in the figure is greatly expanded compared with the r coordinate.

Point-Source to Point-Source Reflectors

For some applications, it is desirable to produce a virtual source from a given real source. For example, it may be desirable to position a real source at the vertex of a paraboloidal reflector and utilize some surface between the vertex and the focal point that images the real source into a virtual source located at the focal point. The resulting antenna system, a counterpart of the optical Cassegrain system, will then have a focused beam, since the paraboloid is energized by a source that is apparently at the focal point.

FIGURE 15-41 Geometry of hyperbola reflection

It is first obvious that the reflector surface desired must be symmetrical about the axis joining the two sources. If a cross section of the reflector is known, the complete surface can be formed by rotating this reflector arc about the axis. Figure 15-41 indicates the geometry of the two-dimensional problem. The reflected rays should appear to originate at the point v , or, in other words, rays from the real source shall be reflected to form a spherical wavefront with its center at v . Since in the figure we require that $A + B$ be a constant and $r + B$ should be a constant, we find that the surface is determined by the fact that $A - r$ is a constant. From analytic geometry, it is known that the locus of points satisfying this condition is a hyperbola. The curve can then be written as

$$r = \frac{a^2 - c^2}{a \pm c \cos \theta} \quad (15-30)$$

The quantities here are indicated in the figure. The plus-or-minus sign corresponds to two possible reflector surfaces, one concave and one convex.

Another possible reflector for translating a point source into a point source is an ellipsoid. The ellipse cross section is given by

$$r = \frac{a^2 - c^2}{a \pm c \cos \theta} \quad (15-31)$$

where the quantities are the same as in Figure 15-41.

For application to the paraboloidal reflector mentioned in the first paragraph of this subsection, three surfaces, namely, the ellipsoid and the two hyperboloids, are possible. For practical application, the ellipsoid, which must be mounted at a greater distance from the reflector, is not satisfactory. Of the two hyperboloid surfaces, the one that can be mounted farther from the reflector illuminates typical reflectors better than the nearer, which requires a paraboloid with large F/D ratio. When the real source is moved from one focal point of the hyperboloid system, the image source will move away from the other focal point but will, at the same time, become distorted. Any great motion of the real source produces a poor image.

Point-Source to Line-Source Reflectors

It has been mentioned that the parabolic-cylinder reflection will convert a point source into a line source. However, this property is not unique for this reflector. Other surfaces⁵⁵

capable of accomplishing the same result have been designated as hyper and elpar surfaces. These have principal plane sections that are hyperbolas, parabolas, and ellipses. It can be seen that in the plane of the parabola, rays from the feed source can be focused to be parallel, whereas in the plane of a hyperbola (or an ellipse), the rays can be reflected so that they appear to come from a virtual-source point. This does not prove that the reflected wave is a cylindrical wavefront, but indicates only that the cross sections of this wave in the two principal planes correspond to those of a cylindrical wave. A general reflector can be obtained by assuming that the point source lies at the coordinate value $(d, 0, 0)$ and that the line source coincides with the z axis as in Figure 15-42. By taking a general ray not lying in either principal plane and requiring that it have a constant path length between the point source and the line source, it can be shown that the reflector surface is given by the following expression:

$$\sqrt{(r \sin \theta)^2 + (r \cos \theta - d)^2 + z^2} + r = 2x_0 - d \quad (15-32)$$

or

$$\sqrt{(x-d)^2 + y^2 + z^2} + \sqrt{x^2 + y^2} = 2x_0 - d \quad (15-33)$$

All quantities in this expression are shown in Figure 15-42. If you set θ equal to a constant, it can be shown that all such sections of the reflector are parabolas, whereas setting z equal to a constant yields ellipses in those planes.

A reflector directly related to that indicated earlier involves cross sections that are hyperbolas rather than ellipses. The mathematics is similar. Using the quantities of Figure 15-42, we have the expression

$$\sqrt{(r \sin \theta)^2 + (r \cos \theta - d)^2 + z^2} - r = \pm(2x_0 - d) \quad (15-34)$$

The plus-or-minus signs indicate two possible surfaces, one concave and one convex. Here it can be shown that the phase θ constant intersect at the surface in parabolas and the planes z constant intersect it in hyperbolas.

FIGURE 15-42 Geometry of elpar surface

Conical Reflector⁵⁶

The conical reflector is excellent in applications in which the complexity of a doubly curved large aperture is to be avoided. A simple feed with spherical wavefront is reflected from a unique surface into a conical wave that is reflected from the conical surface as a plane wave. Figure 15-43 shows a cross section of the three elements that are the basis of this system. The elements are the small horn, the small parabolic-arc reflector, and the conical reflector, which in the figure becomes a straight line. The complete system is obtained by rotating the cross sections about the axis. It can be seen that the tilted straight line when rotated about the axis becomes a cone with the center area open. The parabolic arc when rotated produces an unusual surface with a pointed vertex like a cone. The feed structure (small aperture and parabolic arc) blocks the center of the cone to give large sidelobes. An offset version of this system will eliminate the blocking, but the additional mechanical complexity reduces the advantage of using the simple cone.

The design of the conical reflector is based upon two angles: (1) the cone angle and (2) the angle that defines the subreflector. The cone angle is found to be 26° ; the angle defining the subreflector is about 50° . The equation of the generating curve of the subreflector is $\rho = 2F/[1 + \cos(52^\circ - \theta)]$. The zero coordinate of this curve coincides with the phase center of the feed. Ludwig⁵⁶ gives detailed design data that show that the optimum configuration has a usable annular ring of aperture with width 1.25 times the radius of the parabolic-arc reflector. Experimental measurements showed a gain in excess of 40 dBi with sidelobes of -12 dB.

The conical reflector can also be used as a magnifier system in which a smaller aperture radiates a plane wave toward a conical subreflector of equal aperture. The reflected conical wavefront then is used to feed the same conical reflector of Figure 15-43. The concept is essentially the same as that of the figure except that the initial wavefront is a plane rather than the spherical wave from the horn antenna. The magnification gives an increased directivity of the order of 2.5:1.

FIGURE 15-43 Conical reflector

Shaped-Beam, Singly Curved Reflectors

This problem is essentially two-dimensional, so that ray paths can be restricted to a plane and the cylindrical-reflector surface can be obtained from its plane-curve generator. The basic concepts for the design of a singly curved reflector are simple; the desired shaped-beam pattern is obtained point by point from the primary-feed pattern. The problem presented is that of forming the reflector to make any particular segment of primary-pattern energy appear at the desired point in space. Two basic conditions must be satisfied. The first is that of the energy correspondence between primary $I(\phi)$ and secondary pattern $P(\theta)$, which can be expressed as

$$\frac{\int_{\theta_1}^{\theta} P(\theta) d\theta}{\int_{\theta_1}^{\theta_2} P(\theta) d\theta} = \frac{\int_{\phi_1}^{\phi} I(\phi) d\phi}{\int_{\phi_1}^{\phi_2} I(\phi) d\phi} \quad (15-35)$$

where ϕ and θ are the primary- and secondary-pattern angles and the subscript values correspond to the reflector limits. The second condition relates the angle of incidence to the radius vector defining the surface:

$$\frac{\rho'}{\rho} = \tan i = \tan \frac{\phi - \theta}{2} \quad (15-36)$$

The relationship between θ and ϕ obtained from the first expression can be substituted in the second expression so that a differential equation is obtained between the radius vector ρ and the feed angle ϕ ; this relationship defines the desired reflector curve.

The most difficult part of the shaped-beam problem is that of computing the desired curve from the preceding expressions. Quite often the first expression must be solved graphically so that the differential equation also requires a graphic solution. If the functions $P(\theta)$ and $I(\phi)$ are integrable, then the first expression can be solved for $\theta(\phi)$ and the second expression becomes

$$\ln \frac{\rho}{\rho_1} = \int_{\phi_1}^{\phi} \tan \frac{\phi - \theta(\phi)}{2} d\phi \quad (15-37)$$

and the integral is evaluated by numerical methods. If the pattern functions are not integrable directly, numerical methods are used. First, a plot is made of the pattern functions. Next, the four integrals in the first expression are evaluated by obtaining the corresponding areas under the curves. For the integrals with variable upper limits, many different values of the area must be found, corresponding to different values of the variable. With this information, it is possible to obtain the two curves of Figure 15-44. These curves are used to obtain the desired value of θ for any given value of ϕ . With this known, $\tan \{[\phi - \theta(\phi)]/2\}$ is plotted and the integral evaluated so that $\rho(\phi)$, the desired curve, can be obtained.

Doubly Curved Reflectors⁵⁷

The problem of beam shaping becomes somewhat more complicated when the reflector is to shape the beam in one principal plane and focus it in the other plane. Since the problem is a 3D one, the possibility also exists that the feed might not produce a simple spherical wavefront but might also yield a cylindrical surface, a football-type surface, or any of a number of other surfaces. Fortunately, all feed systems of interest have a circular wavefront in the plane of beam shaping, so that techniques similar to that employed in the preceding subsection can be utilized to determine the surface cross section in that plane. The existing techniques consist of forming the reflector surface from the plane-curve cross section, which serves as a spine, and a series of other plane curves that are attached as ribs to the spine. Some question has arisen regarding this general technique, but it has been found to produce satisfactory experimental results for cases in which beam shaping is desired over a limited angle. This problem may be studied more carefully for application to beam shaping over wider angles.

FIGURE 15-44 Relationship between feed angle and pattern angle in a shaped reflector

The plane curve, just identified as a spine, has been called the central-section curve. This curve is found in a manner quite similar to that described in the preceding subsection. The design equations for the feed with spherical wavefront are obtained using the same quantities as before:

$$\frac{\int_{\theta_1}^{\theta} P(\theta) d\theta}{\int_{\theta_1}^{\theta_2} P(\theta) d\theta} = \frac{\int_{\phi_1}^{\phi} \frac{I(\phi)}{\rho} d\phi}{\int_{\phi_1}^{\phi_2} \frac{I(\phi)}{\rho} d\phi} \quad \frac{\rho'}{\rho} = \tan \frac{\phi - \theta}{2} \quad (15-38)$$

The major difference between these expressions and the previous ones occurs in the presence of ρ under the integral sign. The integration can be carried out as before if first ρ is assumed to be a constant over the shaped portion of the central-section curve; then follow a parabolic arc [$\rho = \sec^2(\phi/2)$] over the region that produces the main beam. With this assumption, the procedure is identical with that of the last subsection for obtaining the function $\rho(\phi)$. This function represents a closer approximation to the correct value than the original assumption. When it is used as the value under the integral sign and the entire procedure is repeated, a new value of $\rho(\phi)$ that is as close to the true value as necessary in any practical case is obtained.

A discussion of the rib curves will indicate the limitations in the present techniques. To obtain the ribs, it is customary to consider an incoming bundle of rays from the secondary-pattern angle θ . For beam shaping in the vertical plane, this bundle of rays is confined to a plane making an angle θ with the horizontal plane. It is required that the reflector surface direct these rays to the feed position. Figure 15-45 shows two parallel rays in this plane that intersect the reflector in the curve AA' . The rays between the points A and A' are reflected to lie on a conical surface with apex at the feed.

FIGURE 15-45 Geometry of a 3D shaped reflector

If we considered the transmit case and a plane sheet of rays emanating from the feedpoint, they would intersect the reflector in a curve AA' , and the reflected rays would lie on a cylindrical surface tilted at an angle of θ with the horizontal plane. It should be apparent that although they have the same endpoints, the plane curves AA' are not the same for the transmit and receive cases. This can be understood since it is known that if focusing is desired, the reflector surface in the neighborhood of the points of ray incidence must be a paraboloid. The plane curve cut by this paraboloid will be different if we consider the intersection caused by the transmit plane passing through a focal point and that caused by the receive plane inclined at an angle θ to the horizontal. It is difficult to make a choice between the two curves, although the great majority of existing efforts have chosen the receiving-plane case. A compromise solution might be the plane bisecting the angle formed by the transmitting and receiving planes. The parabolic curve for the receive case mentioned earlier is

$$y^2 = 4z\rho \cos^2 \frac{\theta + \phi}{2} \quad (15-39)$$

Here z is the coordinate measured from the point A' away from the reflector, and y is the orthogonal coordinate. It should be noted that each of the rib curves is a parabola lying in a different plane; when the reflector surface is formed, the planes of various parabola ribs must be inclined at the corresponding angles.

All the previous expressions yield only normalized coordinates for the surface; these must be converted to usable dimensions before the reflector can be constructed. It is desirable to make the central-section curve as large as possible in order to minimize the diffraction effects on the shaped-beam pattern. In the other plane, the reflector size is chosen to produce the desired beamwidth. The feed angles associated with the reflector are chosen in a manner similar to those of the simple paraboloid. It is desirable that the aperture illumination be 10 dB down at the reflector edges.

The most advanced technique⁵⁸ for defining the reflector for beam shaping permits beam control in both principal planes. A two-variable generalized far-field pattern is used to define the reflector surface. The generalization is achieved by replacing the ray-to-ray correspondence by a curve of incident ray directions related to a curve of reflected ray directions.

The caution in the use of any ray relationship is that it ignores diffraction effects. Therefore the reflector defined by geometrical optics should be checked by defining the phase and amplitude across the reflector aperture and integrating for the far-field patterns.

Shielded-Aperture Reflectors

In some applications it is desirable to have very low sidelobes from a pencil-beam reflector. In this instance, considerable improvement can be obtained by the use of metal shielding around the reflector aperture (see Figure 15-46). The typical sidelobes are at about 0 dBi, which for most reflectors represents a value of the order of -30 to -40 dB below the peak gain. With a shielding technique, the far-out sidelobes can be reduced to -80 dB.

This simplest approach to shielding the reflector is a cylindrical "shroud," or tunnel, of metal around the edge of a circular reflector (see Figure 15-46). If the aperture is elliptical in cross section, an elliptical cylinder can be used. The tunnel forms a waveguide of large cross section with the paraboloid at one end. The radiated energy has low levels of current on the outside edge of the tunnel and so has little radiation at wide angles from the beam. There is energy in the waveguide that leaves the feed horn to reflect from the inside of the cylinder. This energy is then reflected by the paraboloid into angles away from the axis.

An improved shielding system that eliminates the reflection of the feed-horn energy is shown in Figure 15-47 as the *horn reflector*. The two versions employ a pyramidal horn and

FIGURE 15-46 Shielded-aperture reflectors

FIGURE 15-47 Geometry of horn reflector

a circular-waveguide horn. These antennas are discussed in other chapters. The variation among cornucopia horns is associated with the variation in aperture illumination. In many applications, the low sidelobe capability is associated primarily with the horizontal plane where interfering sources are found. The circular aperture will give reduced lobes, and the diagonal aperture (see discussion of aperture illumination in the preceding subsection) will give the best performance. The references for experimental cornucopia design are given in other chapters.

The final shielded horn to be considered is the casshorn,⁵⁹ which uses a secondary reflector to replace the horn structure in the cornucopia. The secondary reflector is designed in the same manner as the Cassegrain system. In the lowest-cost version the reflector is plane.⁶⁰ The aperture of the casshorn can be formed in a variety of ways according to the illumination concepts discussed earlier. An elliptical aperture can be designed as easily as a trapezoid or circular aperture. The feed for the casshorn is mounted at one edge of the aperture (see Figure 15-46). The problems in the design are associated with making sure that the feed pattern is not distorted by the nearby reflector surface.

A comparison of the casshorn and the cornucopia indicates that the free-space feed of the casshorn be used to provide more illumination taper for the aperture (particularly in the E plane) than the cornucopia. However, the casshorn has not proved to be superior to the cornucopia in sidelobe performance. Greater application of shielded antennas can be expected as the number of microwave installations increases.

15.6 PASSIVE REFLECTORS

Some reflector systems do not contain a feed source. These reflectors, which are called passive, usually receive and reflect a plane wave. There are three general types of passive reflectors: (1) those used in microwave links, (2) those used as radar targets, and (3) those used in a beam waveguide.

Microwave Relay

The passive reflectors⁶¹⁻⁶³ used in microwave links can be classified as repeaters or periscopes. The first reflector system controls a plane wave in the horizontal plane, and the

FIGURE 15-48 Variation of (normalized) mirror length with α and θ for single- and double-mirror passive repeaters

second controls the plane wave in the vertical plane. The design information for repeater reflectors given in Figure 15-48 shows the geometry of a single-reflector and a dual-reflector repeater system. The reflector surfaces should be within $\lambda/16$ of a plane. The extent of the plane surface should be minimized to reduce costs. The figure shows dual and single reflectors with the dimensions required for various angles of the ray paths. The path loss for the two systems can be calculated by assuming that the projected area seen by the transmitter and receiver is the same (and assuming that in the case of the two-reflector system all the transmitter energy captured by one reflector is reflected from the second reflector). If the ranges from the transmitter and receiver are given by d_t and d_r , then the path loss is

$$10 \log \frac{\lambda^4 d_t^2 d_r^2}{A_T A_R A}$$

where the areas are designated for transmitter, receiver, and projected area of the repeater plane surfaces.

The periscope reflector system uses a large reflector at the top of a tower and a smaller reflector on the ground. This antenna can employ a plane reflector or a curved reflector at the top of the tower. The gain obtainable from the two type surfaces is shown in Figures 15-49 and 15-50.

FIGURE 15-49 Relative gain of a periscope antenna system employing a plane elevated reflector

FIGURE 15-50 Relative gain of a periscope antenna system employing a curved elevated reflector

Radar Targets⁶⁴

Radar targets are passive reflectors that have a reflected-signal distribution similar to the patterns of an antenna. A number of classical targets are given in Figure 15-51. The basic problem in the design of radar targets is that of maximizing the target return.

TYPE	DIMENSIONS	MAXIMUM		ANGULAR RESPONSE	
		A_T	σ	θ	ϕ
SPHERE		$\frac{a\lambda}{2}$	πa^2	360°	360°

FIGURE 15-52 Effect of error in all three corner angles upon a trihedral echo response. Incident radiation is parallel to the symmetric axis.

Mechanical tolerances of the reflector surface limit the performance. For targets of the order of 20λ in extent, a $\lambda/3$ error in the edges will give a loss of 3 dB in the returned signal compared with a perfect target. Figure 15-52 shows the loss for three different corner reflectors for angular errors of the order of 2° .

The simple corner reflector is usable over an angular sector of about 30° . For a wider-coverage angle, an array of corner reflectors can be employed, or the Luneburg lens can be used with a spherical cap reflector⁶⁵ (see Figure 15-53). The figure shows that the maximum-coverage angle is of the order of 120° . Another lens that gives a theoretical return from all directions has been developed. This lens was fabricated by Emerson & Cuming, Canton, Massachusetts. The index variation is given by $n^2 = (2 - r)/r$. The dielectric constant required for small r becomes very large (at quarter radius the value is 7.5). It is possible to replace the center of the lens by a metallic sphere in order to avoid the large dielectric constant. The center portion represents only a small portion of the aperture, so that an operable system could be achieved without the expense of specialized dielectrics.

For coverage in all directions of space, a combination of 20 corner reflectors (duodecahedron) has been successfully tested.⁶⁶ The difficulty in obtaining reproducible lenses has made this reflector approach more satisfactory.

Beam Waveguide

The final use of passive reflectors is in earth stations, where typical waveguide losses cannot be tolerated. The beam-waveguide concept uses a series of large-aperture reflectors

FIGURE 15-53 Lens reflectors: (a) 90° cap, (b) 180° cap, and (c) no cap

FIGURE 15-54 Geometry of a beam-waveguide feed system

to transmit energy with little loss. Initial work on such waveguides⁶⁷ used lens-type apertures. The best existing beam waveguide uses a series of paraboloids, hyperboloids, or ellipsoids. The energy is carried along the guide from one focal point to another, and at each focal point it is received from one reflector aperture and transmitted to the next reflector.

Figure 15-54 shows the geometry of the most effective beam waveguide. The reflectors used are either paraboloid-paraboloid or ellipsoid-hyperboloid.^{68,69} With the configuration chosen, it is possible to eliminate rotary joints in the transmission line. There is very little loss in beam waveguides, and they can be shielded from external signals by the use of large metallic cylinders that encase the beams as they travel between reflectors.

Polarization-Sensitive Reflectors⁷⁰

One or more reflectors in an antenna system can be made up of linear parallel reflectors that will reflect one polarization and transmit the orthogonal polarization. Such reflectors are called *transreflectors*. When they are aligned with the linear reflecting elements at 45° to the incoming polarization, half of the energy is passed and half is reflected. A second solid reflector will redirect the transmitted energy back through the linear elements with a phase that depends upon the spacing between the linear elements and the solid reflector. A spacing of one-eighth wavelength creates a 90° phase shift and circular polarization. A spacing of one-quarter wavelength creates a half-wave phase shift and a reflected polarization at 90° from the incident polarization. This system is called a *twist reflector*.

A transreflector can be used as a focusing device that has 360° coverage in the azimuth plane. The linear elements are aligned at 45° , so that half of the incident linear or circular polarization is passed and the remainder is scattered. The reflector appears as a dome that in the azimuth plane shows the near-side linear elements to be orthogonal to those on the far side. Therefore, the energy that passes through the near side of the dome is reflected at the far side.

If the surface contour matches a sphere (helisphere) or parabolic torus, the energy that reflects from the far side is focused.

The transreflector in a planar configuration can be used to provide two-feed systems in a single reflector. That is, a horizontally polarized signal can pass through vertically polarized reflecting elements. The transreflector can be placed between a paraboloidal reflector and the horizontally polarized feed at the focus. A second, vertically polarized feed can be placed at the image of the focal point in the plane reflector. This has been termed *focus splitting*.

A unique use of the transreflector and twist reflector lies in providing a thin focusing system with a very low F/D ratio.* The paraboloid with focus in face has an F/D ratio of 0.25. A transreflector mounted across the face of the curved reflector will return the energy to the curved paraboloidal surface, where it is reflected. If this surface is a twist reflector, the reflected radiation is shifted through 90° in polarization so that it now passes through the transreflector. The parallel beam of rays from the system was created by reflection at two curved surfaces (two uses of the twist-reflector surface), and therefore the surface curvature required is reduced. The F/D ratio is reduced to 0.125. A further reduction in the F/D ratio is obtained if a Cassegrain subreflector is added and the feed is placed at the vertex. The F/D ratio then is 0.08.

The transreflector or the twist reflector is made up of about ten linear elements per wavelength. Accurate planar surfaces can be easily obtained by printed-circuit card techniques. Curved surfaces are best formed with the same technology, and for this reason polarization-sensitive reflectors are most often used for physically small surfaces.

Frequency-Sensitive Reflectors^{71,31}

It is possible to design a reflector that will pass signals of one frequency band and reflect signals of other frequencies. These reflectors are called *dichroic* or frequency-sensitive surfaces (FSS). Such reflectors are made up of a large array of closely spaced resonant elements. Slots or dipoles can be used. The dipoles reflect the chosen frequency band, and the slots transmit this band. When the dipoles become small compared with a wavelength of interest, there is limited reflection and most of the energy is transmitted. When the slots become small compared with the wavelength of interest, the energy is almost totally reflected. By a proper choice of dipoles or slots, the pass-band can be at a higher or lower frequency than the second band of frequencies.

The most important constraint in the design is the spacing between the two bands of frequencies. If there is an octave band or less, the design becomes difficult and greater losses are introduced. If two octaves separate the bands, the design restrictions are not severe. For sharper response between frequency bands, it is possible to use two or more surfaces, in a manner analogous to transmission-line filter design. The remaining serious design problem is associated with polarization. The surface should preserve the incoming polarization for any angle of incidence. Most surfaces have a different response to polarization in the plane of incidence than to orthogonal polarization.

Polarization limitations have ruled out simple patch and crossed dipole elements in the frequency-sensitive array. The two most widely used elements are the *tripole* and the *Jerusalem cross* (see Figure 15-55). These elements can be more tightly packed in an array. The support of these elements presents a practical design problem since the substrate dielectric will distort the design. Thin Mylar or Kevlar is used for the array, and foam dielectric is used for support of the reflector array.

15.7 LARGE-APERTURE REFLECTOR ANTENNAS

Introduction

Reflector antennas with electrically large apertures, greater than 60 wavelengths, became relatively common in the 1970s. The design of such antennas is dominated by considerations of geometrical optics,^{72,73} which are often refined by considerations of physical optics.^{74,75} There remain parameters of concern: gain, beamwidth, sidelobe level, polarization and cross polarization, antenna noise temperature, and, if more than one beam position is needed, the variation of these parameters with scan angle. The feed design or, in the case of more complex antenna optics, the design of the feed system and subreflector, intimately affect the parameters through illumination control, feed polarization properties, and spillover past the subreflector or the main reflector. Finally, the very structural design affects electrical performance through the scattering of energy from surface-panel irregularities and interpanel gaps, from subreflector and/or feed-support spars, and from the correlation of this scattering arising from the structural design and alignment procedures.

Since the birth of satellite communications, satellite-borne antennas have steadily increased in gain and complexity.⁷⁶ Higher gain derives from a need to increase EIRP in a power-limited environment.⁷⁷ Complexity may derive from several sources such as beam shaping or reconfigurability.⁷⁸ Both lead to large reflectors. Currently, reflectors electrically as large as about 200 (ACTS) and mechanically as large as 12 meters have been launched. Even larger antennas are planned for future applications. Electrically large reflectors are usually fed by simpler antennas such as horns or arrays of horns or by folded-optics systems involving subreflectors and feeds. In many instances, the antennas are designed to produce two coaxial beams with orthogonal polarizations over near-octave bandwidths. The feed systems may then terminate in complex microwave circuits involving polarizers and orthomode transducers to separate or combine orthogonally polarized beams as well as in microwave multiplexers to separate or combine different frequencies.

Electrically large reflector antennas have their principal applications in radar, where their high gain and narrow beamwidths enhance radar range and angular resolution; in radio astronomy and other deep-space applications, where the same parameters enhance sensitivity and resolution of stellar radio sources; and in microwave communications, where high

gain, low noise, and sidelobe control enhance effective radiated power relative to isotropic (EIRP), receive sensitivity, and isolation from interference. For reflector antennas of diameter greater than 60 wavelengths, gains range from 40 dBi to about 70 dBi, half-power beamwidths (HPBW) from about 1.5° to about 0.05° , and average wide-angle sidelobe levels down to -20 dBi (almost 90 dB below the peak of the main beam); dual-polarized radiation-pattern orthogonality provides isolations greater than 33 dB over the HPBW. Of course, these properties depend upon the feed system as well as the reflectors.

Pencil-Beam Reflector Antennas

This section discusses characterization methodology for pencil-beam reflector antennas by incorporating various design options and comparing the performances of single and multi-antenna configurations.

Front-Fed Paraboloidal-Reflector Systems

The paraboloidal-reflector antenna and its design are described earlier in this chapter. Since the design is geometry-controlled and since the larger electrical apertures considered here make geometrical-optics considerations even more valid, the choices of F/D ratio, edge taper, etc., remain the same. However, the simple front-fed reflector has disadvantages due to the blocking of the aperture by the feed system and by the feed supports.^{79,80} Figure 15-56 shows two views of a front-fed paraboloidal-reflector antenna with feed supports extending

FIGURE 15-56 Front-fed paraboloidal-reflector antenna

from the reflector edge. It is seen that the feed supports intercept radiation reflected from the paraboloid. (Supports that are not on the edge intercept energy from the feed before it reaches the reflector.) In a geometrical-optics sense, the feed supports cast a shadow upon the aperture plane, shown in the third view. This shadow, called *aperture blockage*, reduces gain and affects near-in sidelobes, raising some and lowering others. In addition, the blocked radiation is scattered by the feed supports and can significantly increase wide-angle sidelobes. In general, the front-fed design with a simple feed horn has less blockage than the folded-optics designs. Additionally, the feed subtends a wider angle at the main reflector than a feed illuminating a subreflector does, and therefore the feed is a simpler, lower-gain design. However, if the feed system is complex and the microwave package abutting it is large and heavy [containing polarizers, orthomode transducers (OMTs), low-noise amplifiers (LNAs), etc.], the blocking advantage is negated somewhat. Further, the focal point is an awkward location for such electronic gear, both structurally, because the weight is not desirable at the end of a large-moment arm, and from the point of view of equipment servicing. Finally, in electrically large reflectors, in which reflector size must be minimized, the folded-optics system can be made more efficient. The front-fed reflector has an efficiency of 55 to 60 percent. Folded-optics designs can employ shaped subreflectors to increase efficiency.

Folded Optics

Pencil-beam reflectors may be illuminated by feed systems in which the path of energy from the feed (which terminates the guided-wave-waveguide assembly) is reflected by one or more subreflectors. Figure 15-57 portrays the geometry of the Cassegrain reflector system, whence it is seen that the incoming-ray trajectories are folded back in the direction of the vertex of the paraboloid P by reflection from the hyperboloidal subreflector H . The focusing properties of the system derive from the collocation of one focus of the hyperboloid H with that of the paraboloid at F_1 . An incoming plane wave from the direction of the paraboloid axis is reflected from the paraboloid and from the hyperboloid and focuses at F_2 , the other focus of the hyperboloid H . A feed with its phase center at F_2 will then receive the incident energy.

FIGURE 15-57 Cassegrain geometry

FIGURE 15-58 Gregorian geometry

Figure 15-58 portrays the geometry of the gregorian reflector system. Here the subreflector is an ellipsoid E with its near focus collocated at F_1 with the focus of the paraboloid, the ellipsoid lying on the side away from the paraboloid vertex. The phase center of the feed should then lie at F_2 , the other focus of the ellipsoid. Another configuration is shown in Figure 15-59. Here the subreflector is paraboloidal, with its focus collocated at F with the focus of the paraboloidal main reflector. The result of the reflector of the rays representing the incoming plane wave is a collimated cylinder of rays parallel to the axis. This creates the possibility of another, smaller aperture plane parallel to XX' . A feed system associated with this aperture would have a plane wavefront, or the parallel rays could be associated with an appropriate beam-waveguide system.

An immediate advantage of all three folded systems is that the feed system is now located nearer the vertex of the main reflector and, in fact, can usually be reached from access provisions at the vertex. More subtly, introduction of the additional reflection at the subreflector provides an additional degree of design freedom. Aperture distribution can be controlled to increase efficiency and decrease blockage by shaping the subreflector and the main reflector so that the surfaces deviate from the hyperboloid, ellipsoid, and paraboloid.

FIGURE 15-59 Planar-feed field geometry

FIGURE 15-60 Blockage by feed and subreflector

The Cassegrain system is more compact than the gregorian system for the same focal length. There have been claims that gregorian systems provide improved wide-angle sidelobes in apertures of the order of 200 wavelengths. However, because of blockage of the feed system, subreflector, and supports, the sidelobes of these folded antennas are not especially low. By careful design and construction, the sidelobe envelope can be made to conform to international and Federal Communications Commission (FCC) requirements. For example, INTELSAT old Standard A antennas, which have gain in excess of 57 dBi (generally 60 dBi), require sidelobe envelopes to be less than $(29 - 25 \log \theta)$ dBi, from 1° to 48° , and less than -10 dBi beyond 48° . (θ is the pattern angle measured in a band of $\pm 1^\circ$ about the geostationary arc.)

One of the design principles used in minimizing subreflector and feed blockage is to make them equal, as shown in Figure 15-60. The subreflector blocks incoming rays, and the feed blocks rays that would hit the main reflector and be reflected to the subreflector. For the case shown, the shadows of the feed and subreflector intersect on P, the paraboloid main reflector, presenting the ideal case.

It has been found that keeping the subreflector diameter small (10 percent of the diameter of the main reflector) will keep the central-blockage sidelobes from exceeding the specifications given earlier. If this is not done, the sidelobes are high in the 1° to 10° region. The subreflector support spars tend to create sidelobe problems in a region of 5° to 20° in the plane perpendicular to the spars. It has been found useful to use a spar quadruped with all spars at 45° to the plane of concern. However, the best way to reduce sidelobes is to eliminate the blockage by the use of offset reflectors.

Sidelobes in Electrically Large Antennas

Sidelobes in a folded-optics system arise from a number of sources. These include (1) radiation-pattern sidelobes from the aperture illumination, (2) spillover and edge diffraction from the subreflector illuminated by the feed system, (3) spillover and edge diffraction from the main reflector illuminated from the subreflector, (4) central blockage (subreflector and feed system), (5) spar (subreflector support) blockage and scattering, (6) deviation of reflector surfaces from the desired contours, and (7) effects of gaps between panels.

Control of aperture illumination amplitude and phase to reduce sidelobes dates back to the earliest days of antenna theory and practice, and many references can be found in any basic antenna text. More recent techniques are discussed in two review articles.^{81,82} One approach that has become quite important is the use of offset geometry, yielding an unblocked aperture that eliminates sidelobes arising from central blockage, spar blockage, and spar scattering. This will be discussed in greater detail next.

Departure of the aperture illumination in amplitude and phase from that desired can arise from feed-aperture phase errors⁷⁹ and defocusing.⁸⁰ These will cause the radiation (diffraction) pattern to depart from the design values, but are correctible by careful feed design and positioning. Spillover and edge-diffraction effects can be avoided by illumination of the subreflector with a more deeply tapered feed pattern to about 20 dB down at the edge. For the shaped subreflector, it is possible to obtain sharp illumination taper at the main-reflector edge.^{83,84} Spillover and edge diffraction of feed radiation will give increased sidelobes in the 10° to 20° region of the pencil-beam axis.

Minimizing the central blocking and optimizing the illumination are not compatible, since the first requires smaller feed systems and the second requires larger feed systems. Equalizing the subreflector and horn blockage as discussed in the preceding subsection is the best approach. Then if the subreflector diameter can be kept to less than 10 percent of the main-reflector diameter, shaping is possible and the blockage lobes will meet the sidelobe criterion of the preceding subsection. Central blockage casts a wide beam inversely proportional to the diameter of the central blockage and thus typically ten times the beam-width and 20 dB down from the main beam. It is out of phase with the main beam and thus subtracts a fraction of 1 dB from the main beam, adds 2 to 3 dB to the first sidelobe, subtracts from the second sidelobe, etc. Spar blockage and scattering^{79,85} are not circularly symmetrical and depend upon spar shape and spar-reflector-subreflector geometry. If the spars are not mounted at the dish edges, shadows are cast on the main reflector to reduce efficiency, and blockage of the reflected energy is still present. Spar scattering effects are strongest in the forward hemisphere at an angle of $180^\circ - \xi$, where ξ is the angle between the spar axis and the aperture plane.⁷⁹ The sidelobes are strongest in the forward direction in the plane containing the spar and the beam axis. This typically occurs in the region at 5° to 15° off the main-beam axis. Spar design can minimize but not eliminate this effect. Streamlining the spar cross section is useful for the polarization perpendicular to the spar. Orienting the spars in a quadruped at 45° to the horizontal is effective for earth stations in keeping spar-induced sidelobes out of the region of the geostationary arc. Figure 15-61 shows the effects of central blockage, spar blockage, and forward (subreflector) spillover on a radiation pattern.

The remaining two sources of sidelobe energy derive from the manner in which electrically large antennas are fabricated, assembled, and installed. Most electrically large reflectors are constructed of segments (panels) assembled onto a backup structure or with the backup structure as an integral part of the panels. The subreflectors are generally single units.

The rms errors associated with fabricating a single panel or a subreflector can be controlled with care to 0.1 mm (4 mils) for a reflector or panel up to 3 m across; however, commonly used fabrication techniques permit rms errors of 0.25 to 1.27 mm (10 to 15 mils) for panels of this size. Assembly and installation errors are each of the same order, provided careful checkout procedures are used. A rule of thumb for communication and radar reflectors in the 8- to 30-m class is that the ratio of rms error to reflector diameter is 2 to 5 times 10^{-5} . Some electrically large antennas have been built to better tolerances for radio astronomy, but they usually require special protection from the environment. The pattern effects of the errors depend upon their statistical nature.^{79,86-89}

It has been shown⁹⁰ that when error correlation intervals are small, the results obtained by Ruze^{86,87} for axial gain apply (see Figure 15-62). However, because panel-fabrication error contributions tend to be of the same order or smaller than assembly and installation

FIGURE 15-61 Blockage effects on sidelobe structure

FIGURE 15-62 Normalized loss due to finite surface error

error contributions, the large correlation errors of the assembly can dominate. Therefore, you cannot reasonably assume small correlation intervals in most large antennas. Bao⁹⁰ has shown that the effect of these large correlation intervals is to reduce the gain loss and that the sidelobes are significantly lower than predicted under Ruze's assumptions regarding correlation. In a similar fashion the distortions due to wind and gravity have long correlation intervals and hence less effect than predicted by the small-correlation-interval theory. The large correlation intervals increase the sidelobes in the region near the main beam, while the small correlation intervals (random errors) contribute significantly to wide-angle sidelobes. Papers by Rahmat-Samii et al.⁹¹⁻⁹⁴ and a review paper by Corkish⁹⁵ on the effects of reflector surface distortions on sidelobe levels cover the various approaches to this subject in some detail and provide a wealth of references.

An excellent treatment on very large earth station antenna sidelobes was given by Korvin and Kreutel,⁸⁰ who presented results of both theoretical and measured studies for apertures ranging from 100 to 600 wavelengths. Figure 15-63 presents some of these results.

As real-time control techniques and data processing have become more capable in the past decade, the possibility of correcting for distortions has become a reality. Real-time adaptive optics for optical telescopes was demonstrated in 1989, mainly to remove distortion due to the atmosphere.⁹⁶ Adaptive phased-array feeds can be used in a similar manner to compensate for deterioration of scanning.⁹⁷ Schell's multiple antenna,⁹⁸ while invented for other purposes, embodies all the necessary characteristics for adaptive removal of both atmospheric and surface distortions. The advent of modern control electronics and drive mechanisms should make the multiple antenna a candidate approach for large-aperture reflectors.

The increased interest in large, spacecraft-borne antennas and in sidelobe control has given rise to increased interest in and use of offset configurations, especially for multibeam and scanning applications.^{99,100} The conventional pencil-beam Cassegrain and gregorian configurations have been studied to provide design techniques for the offset cases.¹⁰¹⁻¹⁰³ A technique for increasing antenna efficiency by extending the subreflector in an offset Cassegrain antenna has been analyzed.¹⁰⁴ When offset Cassegrain or gregorian reflector systems are used in beam-scanning or multibeam applications, feeds must be moved or located in the positions that provide optimal beam performance. This turns out to be a hyperboloid for the offset Cassegrain^{105,106} and an ellipsoid for the offset Gregorian.¹⁰⁷

High-Efficiency Dual-Reflector Systems

Electrically large pencil-beam antennas are costly. Cost is almost a linear function of aperture area (reflector surface). The higher the efficiency, the smaller the aperture required to collect incoming waves or to provide gain for a transmitted wave. Antenna efficiency is the product of a number of factors, each of which represents the degree with which the energy is protected against diversion from the desired direction or polarization by a particular mechanism. The factors include effects of (1) aperture illumination (η_i), (2) spillover around the main reflector and subreflector (η_{s1} , η_{s2}), (3) blockage (η_b), (4) reflector-surface deviations (η_r), (5) polarization purity (η_p), and (6) losses in waveguide and feed (η_0). These efficiency factors are defined in Table 15-1.

Spillover, blockage, and surface tolerance effects have been discussed earlier in terms of sidelobe control. Improvement in efficiency and reduction of sidelobe effects go hand in hand for these factors. Polarization purity is controlled by feed-system polarization properties, by curvature of the reflector, by symmetry, by scattering properties of the blockage elements, and, for circular polarization, by internal reflections in the waveguide and feed system.

Control of aperture illumination¹⁰⁸⁻¹¹⁰ is a major factor in improving efficiency. Techniques for controlling illumination can also minimize the effects of central blockage,

as will be seen. If maximum gain is desired, the object is to shape the subreflector and the main reflector so that the aperture illumination is as nearly uniform as possible, with minimum spillover and with minimum energy blocked.

Three basic conditions are used to shape the two reflectors: (1) Path length from phase center of feed to aperture plane is constant for all paths. For the j th ray, as shown in Figure 15-64,

$(\overline{F_2 S_j} + \overline{S_j M_j} + \overline{M_j A_j}) = \text{path length from feedpoint to aperture plane} = r_j + z_j + (r_j \cos \theta_j - l + z_j) / \cos \theta_j = \text{constant.}$ (2) Aperture illumination is constant. It can be shown^{109,110} that this requirement leads to

where $E_f = E_f(\theta)$ is the circularly symmetric pattern of the feed horn. (3) Snell's law must apply. This leads to the expressions

These three conditions (four equations) can be solved on a computer to yield the two surfaces desired. But the general nature of the solution can be deduced from the physical problem. It is desirable to make the aperture illumination more uniform when it is too high in the center. If the slope of the subreflector near the center were altered to reflect central rays from the feed away from the center of the main reflector, this would have the desired effect. The dotted curve in front of the subreflector represents such a distortion. The main reflector must now be reshaped to maintain the focused beam. This results in the dotted curve behind the main reflector.

If the process is exaggerated near the middle of the subreflector, a hole would result in the illumination of the main reflector. The energy here is normally blocked by the subreflector so that there is no basic change in the radiation pattern near the main beam. There will be a reduction in the energy scattered by the subreflector and, therefore, lower scattered sidelobes at wider angles. It has been indicated¹¹¹ that you can optimize the shaping of dual-reflector systems for G/T_{antenna} , rather than G alone. Since T_{antenna} has a major component arising from sidelobes intercepting the earth, this entails sidelobe control as well as gain optimization.

At the edge of the subreflector the surface can be shaped to direct energy inward and so give a shorter and deeper illumination taper at the edge of the main reflector to reduce spillover. The shaping of the subreflector edges can compensate for deeper tapering of the energy incident upon this surface. Therefore, a system with less spillover past the subreflector and with under-illumination of the main reflector can use the shaping of the subreflector edges to compensate for the under-illumination. Thus, it is seen that reflector and subreflector shaping not only can improve the aperture illumination but can also reduce spillover past both reflectors.

It has been found that the simple geometrical-optics analysis of shaping is not sufficiently accurate.¹¹² Improved performance can be obtained by considering diffraction effects at the subreflector.⁸⁴ The system improvement has been limited in bandwidth, and a third approach⁸⁴ modifies geometrical-optics design to give good performance over a wider bandwidth.

With the growing popularity of offset configurations, shaping theory has been applied to improve the efficiency of offset-fed dual reflectors. The geometric-optics approach developed by Galindo¹⁰⁸ has been particularized for the Cassegrain and Gregorian configurations¹¹³⁻¹¹⁵ and extended to show that the geometric-optics-based design produces very similar results when geometric-optics-based predictions are compared with those of physical optics and the geometric theory of diffraction in the aperture.¹¹⁶

15.8 DIFFRACTION SHAPING

To overcome the limitations of GO shaping, several methods have been attempted. In an early work,⁸⁴ reflector shaping by diffraction synthesis was carried out using the method of spherical wave expansion (SWE). The more general framework of "reflector surface expansion coefficient optimization" was effectively applied to synthesizing the aperture field using the GO method¹¹⁷ and later employed in methods that incorporate GO algorithm and physical optics (PO) analysis such as Nomoto and Watanabe¹¹⁸ and Bergmann et al¹¹⁹ (the *indirect* method). This concept was further extended to methods that carry out full PO synthesis (shaping) of reflector antennas with circular aperture and single feed, such as the single-reflector contoured beam antennas in Bergmann et al¹¹⁹ (the *direct* method), and the dual-reflector pencil-beam antennas in Nomoto and Watanabe¹¹⁸ and Schlobohm and Arndt.¹²⁰ The expansion functions used in these works, such as the Fourier series and polynomials, are usually heuristically chosen. In the PO diffraction synthesis (shaping) method introduced in Rahmat-Samii and Mumford,¹²¹ a set of orthogonal global expansion functions was applied effectively to represent reflectors with circular apertures. This orthogonal representation will be used and generalized in the diffraction synthesis technique presented in this chapter.

FIGURE 15-65 An overview of the generalized diffraction synthesis technique. The unknown coefficients (C_{nm} , D_{nm} , G_{nm} , H_{nm} , and A_n), which characterize the antenna system, are to be determined using optimization algorithms.

A generalized diffraction synthesis technique that can be used to synthesize single- and dual-reflector antennas with a single feed or an array feed is shown in Figure 15-65. There are several features that distinguish this technique from others. First, the previous notion of “reflector surface expansion and coefficients optimization” has been generalized to “antenna system characterization and parameters optimization,” in which the reflector surface expansion becomes a portion of the characterization process, and the expansion coefficients consist of a subset of the antenna parameters to be optimized. This conceptual generalization allows us to solve the problems of (1) reflector shaping with general array feed and (2) simultaneous synthesis of reflectors and feeds, which are not addressed in the PO synthesis methods published so far.

Another feature that makes the current technique powerful is that the global surface expansion¹²¹ is used and generalized to reflector aperture boundaries that may be circular (elliptical), square (rectangular), or any intermediate rounded-corner shapes described by the superquadric functions.¹²² The shaped reflectors are characterized by having smooth surfaces, well-defined circumferences, and continuous surface derivatives.

Also unique in the method is that the PO/physical theory of diffraction (PTD) technique is used to analyze the antennas. The PTD fringe field^{123,124} is particularly useful when PO analysis is not sufficiently accurate for very stringent requirements on, for example, sidelobe levels at far-angular regions and cross-polarization control. The edge diffraction and near-field effects are included automatically in the course of diffraction synthesis.

The generalized diffraction synthesis technique can be applied to produce various radiation patterns such as pencil-beams and contoured beams, and to improve the radiation characteristics of an existing canonical or distorted system. It is believed that the scope of the application of this technique embraces the majority of commonly used reflector antenna configurations.¹²⁵

16.1 INTRODUCTION

Microstrip antennas were born of microstrip circuit technology and inherited many characteristics, such as low radiating efficiency and narrow bandwidth, that are undesirable for a radiator. However, they offered many desirable features in terms of size, low profile, ease of integration with circuits, and forming arrays. Consequently, research has been conducted to improve their performance as radiators. Fundamentally, there are two types of microstrip antennas: the *traveling wave* type and the *resonant* type. The traveling wave microstrip antennas are for the most part some forms of printed lines that have been modified to radiate more efficiently. Examples are the comb lines, rampart lines, and other microstrip discontinuity lines.¹ These antennas generally have wide impedance bandwidths, but are negatively affected by the frequency dependence of their radiation characteristics such as the beam squint and sidelobe. The resonant microstrip antennas have relatively well-defined radiation characteristics, but suffer from narrow bandwidths. This class of microstrip antennas has received most of the attention in designs and bandwidth improvement. This chapter will provide a summary of the broadbanding techniques and examples of different designs capable of providing wideband characteristics. Since resonant microstrip antennas generally have broader bandwidths for their radiation characteristics like gain, sidelobe, and polarization, the bandwidth in this chapter will refer primarily to the impedance bandwidth of the antenna unless otherwise stated.

Resonant microstrip antennas usually take the form of a conducting printed patch. The patch shape can be arbitrarily determined, but the most common types are rectangular, square, circular, triangular, elliptical, rings, and their derivatives. Because a printed patch is usually over a conducting ground plane, it stores electric charge and energy and acts as a reactive circuit element. Consequently, the impedance bandwidth of a microstrip patch is typically very small, and depending on its substrate parameters and thickness, it can be less than 1 percent, or at best, a few percent. This range of bandwidths is smaller than the bandwidths of other antenna types and is insufficient for most current applications in communication and remote sensing, especially in new areas like microwave and medical imaging. Thus a need has arisen for broadening the bandwidth of microstrip patch antennas. Fortunately, researchers always respond to a challenge, and a number of effective techniques have been developed to increase the bandwidth of microstrip antennas from a few percent to around 50 percent and more, well beyond that of other antenna types. Consequently, microstrip patch antennas are no longer narrowband antennas. However, a price has been paid for broadening the bandwidth of the patch antenna, either in gain, polarization, or in the complexity of the antenna configuration. The drawbacks will be reviewed and discussed in relation with each wideband antenna type.

A number of recent books^{2-4,8} and articles⁵⁻⁷ have surveyed various broadbanding techniques for microstrip patch antennas. These have been referred to here for brevity in lieu of the original papers. There have been two main techniques for broadening the bandwidth of microstrip antennas: the *structural* technique and the *circuit theory* approach. The former deals mostly with the properties of the substrate over which the patch is etched or with the patch shape. The latter uses impedance matching techniques originally developed in circuit theory and then adapted to microwave networks, and here to antennas. However, the relationships are seldom obvious; the application of impedance matching techniques has not been systematic. This is mostly because the majority of broadbanding techniques were found and developed initially by antenna engineers using experimental procedures, and recently by use of commercially available software packages. This is unfortunate, because understanding the principles of impedance matching techniques in circuits can provide analytic methods to supplement the numerical method for determining the most suitable, or at least practically desirable, solutions.

The structural technique has been evolving. Initially, it involved primarily the antenna substrate. Recently, however, it has been expanded to include both the antenna substrate and its geometry, which have commonality with the circuit theory techniques. Microstrip patches are modified in shape and incorporated with slots of various sizes and shapes. Optimization codes have also been used with full wave analysis software to determine patch shapes for given applications. In reality, however, these techniques cause loading of the patch with impedance elements and are implicit applications of the impedance matching techniques.

The major innovation in the substrate area has come from applying the *electromagnetic band gap* (EBG) materials and metamaterials to microstrip antennas. In conventional substrates the ground plane electrical conductivity causes the image effect of the patch and limits its bandwidth and radiation efficiency. With these new materials, which are basically simulated materials using ordinary substrates, other electromagnetic boundary conditions, like a perfect magnetic conductor and a reactive surface, can be simulated. The image effect and the electrical properties of the patch are modified, and consequently the bandwidth and radiation efficiency of the antenna change. Naturally, these phenomena can also be explained and improved by the circuit theory approaches. However, they are easier to implement and understand by antenna engineers using electromagnetic theorems and boundary conditions.

In the sections to follow, antenna bandwidth is defined and related to its input parameters. Then the microstrip antenna bandwidth dependence on its substrate parameters is described. The impedance matching techniques using the circuit theory approach are presented briefly next. Because this method is most effective in enhancing the patch antenna bandwidth, the cases that follow are based on its applications. Sample examples using EBG materials are also provided. References are provided to help in reviewing other designs and innovations not listed in this chapter. Recently, there have been efforts to design ultra wideband (UWB) antennas for new UWB system applications. However, these antennas are required to have dipole-like omnidirectional patterns, not directive like microstrip antennas. For this reason they have not been discussed here.

The impedance bandwidth of a microstrip antenna is determined by its impedance characteristics. However, this is not a useful method in practical application, as the circuit model of the antenna is approximate and changes during the design and experimental tuning. A more practical approach is to define it in terms of its input parameters. The reflection coefficient Γ , or S_{11} , is readily measured by a network analyzer and is commonly used to define the antenna bandwidth. It is also a meaningful parameter, as it signifies the reflected power not available to the antenna, i.e., the *return loss*. Naturally, one is expected to minimize Γ . However, the antenna input impedance is a complex quantity that is also frequency dependent. The situation is more problematic in microstrip antennas because of the uncertainty due to fabrication tolerances in the substrate parameters. For these reasons the return loss of microstrip antennas is normally assumed satisfactory if it is better than 10 dB, and the antenna bandwidth is defined as

$$BW = \frac{(f_H - f_L)_{\Gamma=-10\text{dB}}}{f_o} \quad (16-1)$$

where

$$\Gamma = \frac{Z_{in} - Z_o}{Z_{in} + Z_o} \quad (16-2)$$

and Z_{in} and Z_o are the antenna and feed impedances respectively. Alternatively, the bandwidth is defined in terms of the antenna input VSWR in the form of

$$BW = \frac{VSWR - 1}{Q\sqrt{VSWR}} \quad (16-3)$$

where Q is the antenna quality factor, normally defined in terms of the stored energy and power loss as

$$Q = \frac{\text{Energy stored}}{\text{Power lost}} \quad (16-4)$$

In terms of the return loss, the antenna VSWR is given as

$$VSWR = \frac{1 + |\Gamma|}{1 - |\Gamma|} \quad (16-5)$$

A VSWR of less than 2 refers to a return loss of about 9.54 dB. A lower VSWR of about 1.5 is often desirable and relates to a return loss of about 14 dB. Much lower VSWR values and consequently, much lower return losses, may also be desirable in some applications. However, this can realistically be achieved if the substrate parameters are well defined and the antenna fabrication tolerances are kept low. For these reasons, in this chapter a return loss of 10 dB will be assumed for the antenna bandwidth definition.

16.2 SUBSTRATE EFFECT ON BANDWIDTH

When a patch antenna is etched directly on the dielectric substrate, the permittivity ϵ_r and thickness h of the dielectric influence its bandwidth. For small thicknesses the effects can be estimated intuitively, where the patch antenna can be viewed as a lossy capacitor. Thus the energy stored in the patch antenna increases by increasing the substrate ϵ_r and reducing its thickness h . This increases the Q of the patch antenna and reduces its bandwidth. These effects are shown in Figure 16-1. For $\epsilon_r = 2.2$, as the thickness h increases from

FIGURE 16-1 Effect of substrate thickness and dielectric constant on the impedance bandwidth (VSWR < 2) and radiation efficiency (after D. M. Pozar⁷ © IEEE 1992)

0 to $0.1 \lambda_0$, the bandwidth increases from 0 to 15 percent. For the same thickness, but $\epsilon_r = 10$, the rise in the bandwidth is only about 5.8 percent. The variation of the bandwidth is within expectation, but is not linear, due to other factors such as resistive and radiation losses.

In practice, decreasing the substrate permittivity is feasible and depends on the material selection criteria. However, increasing the thickness h is not as easy or desirable. Substrate modes become excited at discontinuities that scatter at other discontinuities radiating with undesirable polarization and radiation patterns. This phenomenon can become a source of serious performance degradation in microstrip arrays. Higher-order modes of the patch also become excited and contribute to the radiation, again degrading the antenna efficiency, polarization, and radiation patterns. In addition, increasing the substrate thickness also increases the antenna volume, thus increasing its weight and cost. Increasing the substrate thickness h , therefore, is not a good choice for enhancing the bandwidth.

The preceding substrate effects are valid for a patch over a ground plane, which is an electric conductor. The negative image of the patch currents on the ground plane degrades the antenna radiation efficiency and bandwidth. For instance, if the ground plane of the patch were replaced by a magnetic conductor generated using EBG materials, then the ground plane effects would reverse, and the patch antenna radiation efficiency and bandwidth would improve significantly. An example of such a design will be provided later in this chapter. The performance of a simple patch antenna designed to operate over a simulated magnetic ground plane will be compared with that of a conventional patch. Bandwidths in excess of 20 percent are obtained, which compares well with around 3 percent for the conventional patch antennas of similar design.

16.3 EFFECT OF PATCH SHAPE ON BANDWIDTH

The shape of the patch is its main parameter and naturally affects the antenna bandwidth. However, the possibilities are endless and the patch shape also affects its other electrical characteristics such as polarization and gain. It is therefore difficult to provide a general rule and guideline for the patch shape selection entirely based on its bandwidth. In addition, some of the patch shape deformations involve resonant slots that couple to the patch to increase the bandwidth. These configurations act as coupled resonators and are discussed later in this chapter. In this section we address the conventional patch shapes.

For solid patch shapes like square and circle, the bandwidths are nearly the same and proportional to their size. The deviations start when the shape changes significantly and becomes a narrow or wide rectangle. If the radiation edge becomes narrow, the radiation loss decreases and the antenna Q increases, reducing the bandwidth. The opposite is true for a patch with a wide radiating edge. More noticeable effects are found when the central part of the patch is removed to make a ring. Historically, annular ring (or square ring) antennas were considered to be wideband. This is true, however, only for the second mode of the patch, when it operates in the TM_{12} mode. For the first mode, the patch operates in the TM_{11} mode similar to a circular disk, and the antenna is a hybrid of a solid patch and a printed loop. For this mode the antenna bandwidth decreases rapidly as more central conductor is removed, making it a thinner ring.⁹

A more effective means of designing wideband microstrip antennas is by using coupled resonators, which can yield bandwidths in excess of 50 percent. The patch antenna need not be very special, but must be able to couple to another patch or to resonant elements. Resonant elements that are commonly used are a near resonant slot in the ground plane, a resonant slot on the patch itself, or a near resonant feed probe like a bent monopole. This technique stems from the lumped element circuit theory involving the impedance transformation,

specifically in coupled tuned circuits and transformers. If the resonant frequencies of two circuits are the same or nearly the same, then a critical coupling coefficient can be found to match two dissimilar impedances of the generator and load. Much larger bandwidths are obtained if the impedance matching is relaxed and other coupling coefficients are selected.

Note that in using the coupled resonator approach for broadbanding, it is possible to obtain an optimum configuration for wideband match but still fail to achieve the match. This situation usually arises from the presence of reactive components or from the dissimilarity of the patch and the feed impedances. The presence of a loop on the Smith Chart indicates coupled resonators, and the antennas have potential to be broadband. However, the loop may not be centered, due to an extra inductive or capacitive component. When the extra input reactance is removed, the loop moves to the chart center and improves the bandwidth.

16.4 PROXIMITY COUPLED MICROSTRIP ANTENNAS

As indicated earlier, increasing the height of the substrate increases the impedance bandwidth of the patch antenna. However, this causes additional problems, especially in using a transmission line feed. It increases the line width that together with the increased substrate height enhances the feedline radiation. This in turn causes difficulties in array design, where the feed network radiation deteriorates the antenna efficiency and polarization as its radiation is randomly polarized. A solution for this problem is found in using a proximity coupled feed, where the transmission line is etched on a separate lower substrate. In this manner, the parameters of the patch and its feed can be selected separately to optimize their individual performance. For instance, the patch radiation efficiency improves by lowering the permittivity and increasing the thickness of its substrate, but the opposite must be selected for the feedline.

The use of separate substrates for the patch and the feed also allows the use of matching stubs. Two different matching stubs are normally used, one in series with the line at its end, and the other orthogonal to the line before the patch. The end stub is in parallel with the patch input impedance and can influence its reactive component. Consequently, it can be used effectively to move the input impedance loop to the center of the Smith Chart, or to tune the resonance frequency of the patch. Also, its coupling to the resonant circuit of the patch provides a condition for broadbanding. This stub is also located below the patch and its radiation is negligible. The stubs orthogonal to the feedline can similarly be used for broadbanding.¹⁰ However, they are lossy due to the standing waves generated between the stub and patch. Also, the stub becomes a source of radiation that deteriorates the antenna polarization and efficiency. Therefore, it is preferred not to use them for improving the antenna impedance bandwidth.

The original configuration was investigated by Pozar and Kaufman¹¹ (see Figure 16-2). By using a circuit simulator and the experimental data, they showed that the microstrip line coupled to the patch is equivalent to a capacitor in series with the patch RLC equivalent circuit. The size of the impedance loop on the Smith Chart was controlled by the length of the series stub at the end of the line, and an orthogonal stub was used to move the loop to the chart center. Typical results are shown in Figure 16-3. When the tuning orthogonal stub is not connected, the input impedance at resonance is about $40\ \Omega$. Adding the tuning stub moves the impedance loop to the right, where it can be centered to maximize the bandwidth. In this example the height of both substrates was selected to be equal, $h = 0.158\text{ cm}$, and their permittivity was $\epsilon_r = 2.2$. The measured impedance plot gives a bandwidth of 13 percent for $\text{VSWR} < 2$ (3.375 GHz to 3.855 GHz). It was also shown that the orthogonal tuning stub strongly affects the cross polarization, and shorter stubs must be preferred.

FIGURE 16-2 Geometry of proximity-coupled microstrip antenna: Substrate parameters: $\epsilon_r = 2.20$, $d_1 = d_2 = 0.158$ cm. Dimensions: $L = 2.5$ cm, $W = 4.0$ cm, $W_f = 0.5$ cm, $l_s = 0.65$ cm, $d_s = 3.3$ cm, $S = 1.25$ cm (after D. M. Pozar and B. Kaufman¹¹ © IEE 1987).

FIGURE 16-3 Smith Chart plot of measured impedance locus of the proximity-coupled microstrip antenna: (a) with a phase reference at edge of patch, without tuning stub and (b) with a phase reference at stub location, with tuning stub (matched antenna) (after D. M. Pozar and B. Kaufman¹¹ © IEE 1987)

In the preceding design a cross polarization of -20 dB was achieved. The performance of this antenna with different permittivities for the substrates and their heights was later studied in Splitt and Davidovitz.¹² Both rectangular and circular patches were considered, and their impedance bandwidths and efficiencies studied. It was shown that their impedance bandwidth can be increased to as high as 20 percent.

The performance of this microstrip antenna type was further investigated recently by shaping the end stub. In Tethakumary et al¹³ the end stub was bent orthogonally to form an L -shape with the feedline. Its impedance and radiation characteristics were studied experimentally, and an impedance bandwidth of around 20 percent (3.00–3.66 GHz) was achieved. The hook and T -shape^{14,15} stubs have also been investigated, but the bandwidth increase has been marginal. Wide bandwidths were also obtained without tuning stubs but by using parasitically coupled patches (see Legay and Shafai¹⁶). With two parasitic patches, bandwidths in excess of 15 percent at 4 GHz or high gains around 10.3 dBi were obtained and could be increased by adding additional patches. Figures 16-4 and 16-5 show the antenna geometry and its input impedance with two coupled patches.

16.5 APERTURE COUPLED MICROSTRIP ANTENNAS

In the proximity coupled and single-layer transmission line feeds, both feedline and radiating patch are on the same side of the ground plane. These structures are topologically simple and are easier to fabricate or investigate. However, the feedline also radiates in the

FIGURE 16-5 Input conductance of a wideband three coupled patch antenna: o-o-o Theory, + + + Experiment (after H. Legay and L. Shafai¹⁶ © AEU 2002). Parameters: $\epsilon_{r1} = \epsilon_{r2} = 2.5$, $H_1 = H_2 = 1.58$ mm, $L_1 = 22$ mm, $L_2 = 19$ mm, $W_1 = 8.4$ mm, $W_2 = 8.4$ mm, $s_1 = 2.1$ mm.

same direction as the patch and causes deterioration of the antenna gain and especially the polarization. The problem becomes more severe in large arrays, where the feed network grows complex and contains numerous power dividers and impedance matching sections. These junctions generate reflections, surface waves, and multiple resonant modes in the feed circuit. The surface waves, although evanescent, scatter from the nearby junctions and cause radiations with random phase and polarization. The reflected waves, resonant or otherwise, cause enhanced current distributions that increase the feed network loss and alter the power and phase distributions in the array. Consequently, the array gain and efficiency deteriorate and become frequency dependent. Similarly, its sidelobes and cross polarization also increase and become frequency dependent. Thus there is a need for a different feed type. The slot coupled feed is one such feed, where the entire feed network is moved below the ground plane and coupled to the radiating patch through a slot in the ground plane. However, the fabrication of the antenna becomes more complex and costly.

The original slot coupled feed was proposed and investigated by Pozar,¹⁷ where the coupling slot was selected to be small to prevent its radiation. The geometry of this type of antenna is shown in Figure 16-6. Since then, numerous investigators have studied the properties of this structure and have introduced variations in both shape and size of the coupling slot and the radiating patch to improve its impedance bandwidth, gain, and polarization. Zurcher¹⁸ investigated an inverted patch antenna. The patch was etched on a thin dielectric that acted as the protective cover when inverted. The combination was then separated from the ground plane by a thick foam substrate. The slot was enlarged to improve the bandwidth, which was fed by a microstrip line etched on a thin substrate below the ground plane. The antenna was called *SSFIP*, after its structure of Strip-Slot-Inverted Patch, as shown in Figure 16-7. An impedance bandwidth of 11.7 percent for the antenna was achieved that was increased to 21.1 percent for its 4×4 array.

The coupling through the slot was shown to be dependent on the slot shape.^{19,20} In Pozar and Targonski¹⁹ both rectangular and dog-bone-shaped apertures were investigated. In the latter aperture, the rectangular slot was loaded at both ends by half-size transverse slots with rounded corners. The end loading of the slots extended the aperture electric field across the slot well into the slot ends. This extended strong electric field in the slot increases the coupling between the patch and the feedline. In other words, loading the slot ends

FIGURE 16-8 Shapes and dimensions of different apertures (after V. Rathi et al.²¹ © IEEE 1995)

increases its effective length. The coupling efficiencies of different apertures, namely narrow and wide rectangular apertures and *H*, bowtie, and hourglass shapes, were investigated in Rathi et al.²¹ They are shown in Figure 16-8, with dimensions in mm. The antenna was a rectangular patch with $L = 4$ cm, $W = 3$ cm, and the top and bottom substrates were the same with parameters as $\epsilon_r = 4.3$ and $h = 0.16$ cm. The width and length of the microstrip feedline were $W_f = 0.3$ cm and $L_s = 2$ cm. Measured input impedances showed that the end loading and end broadening increase the coupling. They had the opposite effect at the slot center. The bowtie performed better than the rectangular apertures, followed by the *H* and hourglass apertures. In the last case, the hourglass aperture combines the end loading of the *H* aperture with the end broadening of the bowtie, thus providing the strongest coupling.

Further bandwidth enhancement was obtained by using nearly resonant apertures.²² In this manner, the problem is essentially that of two coupled resonators: the coupling aperture and patch. The input impedance plot of the antenna, with its parameters at 5.6 GHz, is shown in Figure 16-9. For $VSWR < 1.5$, the achieved bandwidth is about 23 percent, which becomes nearly 29 percent for $VSWR < 2$. This is considerably higher than the bandwidths achieved by previous configurations and also maintains the quality of its radiation patterns, shown in Figure 16-10 for the copolar component, and in Figure 16-11 for the cross-polar component. Also, within the band the measured gain remained at or above 8 dBi. The significant performance of this design is the fact that its measured copolar contours are symmetric. The measured cross-polarization contours are also symmetric and very low and about -40 dB at the boresight; they remain very low in a large angular range of about 25° about the main beam axis. The cross polarizations in the diagonal planes are maximum at about -15 dB but at large angles off the main beam. These characteristics are due to a strong excitation of the microstrip patch dominant TM_{11} mode and to weak excitation of the higher-order modes.

A further bandwidth enhancement was obtained by using a CPW feedline²³ (see Figure 16-12). It is interesting to note that the coupling aperture is placed coplanar, on the CPW line, and the CPW external ground planes act as the reflecting ground of the patch antenna.

Croq and A Papiernik²² © *Electronics Letters* 1990): $\theta = 0^\circ - 90^\circ$; $D = -1.0$ dB; $C = -3.0$ dB; $B = -10$ dB; $A = -20$ dB. The antenna dimensions are mentioned in Figure 16-9.

FIGURE 16-11 Cross-polar contour plots at 5.6 GHz of the resonant aperture coupled microstrip antenna (after F. Croq and A. Papiernik²² © *Electronics Letters* 1990): $\theta = 0^\circ$ – 90° ; $D = -40$ dB; $C = -30$ dB; $B = -20$ dB; $A = -15$ dB. The antenna dimensions are mentioned in Figure 16-9.

Consequently, this antenna needs only one substrate, and its configuration is simpler. The tuning stub is also placed coplanar with the line and at its end. The CPW structure also makes the active element integration much simpler. A moment method optimization of the antenna provided a wide impedance bandwidth of about 36 percent, at 3.4 GHz, as shown in Figure 16-13. This is larger than the bandwidth achieved by a microstrip line feed, discussed earlier. However, its cross polarization is larger. The measured radiation patterns are shown in Figure 16-14, showing cross polarization around -25 dB, and a front-to-back ratio of 12 dB. The computed gain was 9 dBi.

Designs with ring and U -slot apertures have also been attempted, showing improved impedance bandwidths. An example is shown in Figure 16-15 and Figure 16-16, which uses a ring slot for aperture coupling.²⁴ The patch and slot configurations are complex in shape and use notches for optimization. The feedline end is wider and forms a patch-shaped stub. The configuration was optimized using the moment method software Ansoft Ensemble v8.²⁵ The simulated and measured VSWR results are compared in Figure 16-17, which also shows the antenna dimensional parameters. The H -shaped patch was etched on a thin 1.6-mm FR4 substrate, with a relative permittivity of 4.3. A 50- Ω microstrip line with a tuning stub is located on the lower surface of the lower substrate. A 10-mm air-filled substrate separates the ground plane and H -shaped patch. The structure consists of two resonators: the H -shaped patch and the ring slot. A measured bandwidth of 50.6 percent (2.46 – 4.09 GHz) for VSWR < 2 was achieved. The measured gain remained above 6 dBi in the entire band, as shown in Figure 16-18, and the cross polarization in both principal planes was below -25 dB. However, the measured back radiation was large and about -10 dB below the main beam. To reduce the back radiation, a second ground plane was placed behind the first, with an air

gap of 5.6 mm. With this configuration the antenna impedance bandwidth deteriorated to 44 percent. This indicates that the back radiation is the reason for enhanced bandwidth, which may also be the case for other aperture coupled antennas with large coupling apertures.

16.6 STACKED MICROSTRIP PATCH ANTENNAS

Among various wideband microstrip patch antennas, the coupled patch antennas are simpler to understand and design. Each patch is a resonator and equivalent to an RLC network. Thus two adjacent patches can be viewed as two coupled resonators and can be designed for wideband operation by using the circuit theory approach available in literature and discussed briefly at the beginning of this chapter. For instance, if the resonant frequencies of two coupled patches are nearly the same, then a wide impedance bandwidth can be obtained simply by adjusting their coupling to find the optimum coupling level, which is a single parameter optimization. You should recognize, however, that such a wideband design will not be the true optimum since the parameters of each patch, i.e., each resonator, may not be optimum. In practice, you must optimize the entire antenna geometry, including

the parameters of the coupled patches, together with their coupling level. Nevertheless, the technique of one parameter optimization is a very useful approach in designing coupled patch antennas. When only two stacked patches are used, then a simple adjustment of their vertical spacing provides a quick method of broadbanding their input impedance. In such cases only the lower patch is fed, and the size of the upper patch is made slightly larger to increase its coupling to the lower one.

Coupled patch antennas can be made of two or multiple patches. The case of two stacked coupled patches can be viewed as a single wideband microstrip patch antenna that can be used alone or in an array. Its gain will be slightly larger than that of a single-layered patch, due to its increased height above the ground plane, and controlled by its value in wavelength; that is, the larger the height of the stacked configuration, the larger its gain. This is the secondary benefit from the stacked structure, in addition to its broadband impedance bandwidth. The case of multiple coupled patch antennas can increase significantly both the input impedance bandwidth and the gain.²⁶ However, since such structures are coupled multiple resonators, they can have multiple resonances, some of which can be undesirable. For instance, different patches can have induced surface currents in opposite directions, reducing the gain and increasing the sidelobes. Since the coupling is frequency dependent, such phenomena are also frequency dependent and cause rapid variation of the antenna gain and radiation patterns. Thus multiple coupled patch antennas are significantly more difficult to design and must be investigated carefully.

The coupled patch antennas have fundamentally two different configurations, the planar structures and stacked configurations. Both these configurations were investigated concurrently.^{27,28} In the planar configuration the coupling is from the edges of the adjacent patches. Since the geometry represents two coupled resonators, the coupling coefficient is the most important parameter for broadbanding of the input impedance. However, the coupling in this case is normally weak and below the coupling level necessary for optimum broadbanding. Thus the degree of bandwidth broadening is limited to around 10 percent, unless multiple planar patches are used. Nevertheless, this type of impedance bandwidth increase becomes attractive in the design of planar arrays, like microstrip Yagi arrays, where the planar structure makes this type of impedance broadening very natural. In other cases this configuration becomes appealing only if there is a limitation on the antenna height and adequate planar surface is available for the coupled patches.

The stacked coupled patch structures have been favored in most applications because of the ease with which the coupling coefficient can be controlled by adjusting their separation height. Their other parameters such as the size of the patches and substrate parameters can also be modified independently to facilitate the designs. Consequently, much research has been done on these antennas, and impedance bandwidths of 10–30 percent for $VSWR < 2$ have been achieved. From broadband network theory, if the coupling between the two patches is too strong, i.e., above the required critical coupling, there are two resonance frequencies that increasingly separate by increasing the coupling coefficient. Since in stack patches their spacing controls the coupling, the antenna becomes dual band when patches are too close to each other. As the spacing is increased, the coupling reduces and the two resonances merge at the critical coupling to provide a broadband antenna. Further increase of the spacing reduces the bandwidth gradually.

In practice, the feed network and the substrate parameters also influence the antenna circuit parameters and the bandwidth. Normally, the feed, such as a coaxial probe or an aperture in the ground plane, is also a resonant circuit. Below resonance, they are equivalent to a reactive element and do not introduce additional resonances; however, they affect the circuit parameters of the stacked patches or move the input impedance curve of the antenna on the Smith Chart away from its center. A typical geometry of a coaxial probe-fed stacked microstrip patch antenna is shown in Figure 16-19a,²⁹ where the probe feed inductance is in series with the equivalent circuit of the antenna. If additional matching stubs should not

FIGURE 16-19 Exploded views: (a) dual patch coaxially fed antenna and (b) aperture coupled (after F. Croq and A. Papiernik²² © *Electronics Letters* 1990)

be used to cancel this reactance, then the antenna parameters must be changed to achieve a broadband. Alternatively, the feed location with respect to the patch center may be changed to partially compensate for the reactance. If, on the other hand, the feed size is large and near, or at resonance, within the antenna operating band, then the coupling to the antenna can further increase the input impedance bandwidth. This case corresponds to the near resonance aperture sizes in the aperture coupled microstrip antennas, discussed previously. With conventional probes this phenomenon does not occur, due to small substrate heights of conventional microstrip antennas. It can be introduced by bending the probe to reduce its vertical height. This configuration is also capable of broadband operation and will be discussed in a later section.

From earlier discussions, the lower patch requires stronger coupling and must be on a thin dielectric substrate (thickness $\leq 0.04\lambda_0$), which will also reduce the problems associated with thick substrates, like surface wave losses, weight, and cost. The upper patch requires weaker coupling and should be on a thicker low permittivity substrate ($\epsilon_r \approx 1$ and thickness $\approx 0.06\lambda_0$),³⁰ and is normally suspended in the air or placed on a foam substrate. In such cases, and since optimum couplings require a reasonable separation between the two patches, the upper patch is effectively over a substrate with a permittivity of close to unity. The design process, therefore, becomes somewhat easier. A good starting point is to design the lower patch using the low frequency limit, or for a slightly higher frequency, using conventional design equations. The upper patch in most cases is a few percent larger. The coupling between the two patches pushes the resonant frequency of the antenna toward the required limits. Such a design will be a good starting point for numerical optimization by use of full wave analysis codes. Figure 16-20 shows the effect of the lower and upper patch sizes on the resonance loop on the Smith Chart. Their effects are opposite. As the lower patch size increases, the loop moves to the left toward lower impedance, but for the upper patch it moves to the right and higher impedance.³⁰ Bandwidths in excess of 25 percent are obtained. A larger bandwidth of 40 percent is obtained using a CPW feed of Figure 16-21,³¹ which is nearly the same as the CPW-fed aperture coupled antenna of Figure 16-12.

A drawback of the stacked microstrip patch antennas is the direct radiation from the probe, which becomes significant at high frequencies at large lower substrate heights, especially in cross polarization. This phenomenon can be better understood by comparing the results for both probe and aperture feeding types. Figure 16-19 shows the geometry of these antennas,

Croq et al²⁹ © IEE 1993).

which are a probe-fed stacked patch antenna and a single-layer aperture coupled patch antenna.²⁹ They have impedance bandwidths in excess of 30 percent at 12 GHz. Figure 16-22 and Figure 16-23 provide the measured radiation contours for the copolar and cross-polar components of these feeds at the X-band. The probe-fed antenna shows asymmetry in the contours of both copolar and cross-polar components, due to the probe radiation. They are symmetric for the aperture-coupled antenna.

Croq et al²⁹ © IEE 1993).

FIGURE 16-24 Geometry of multilayered aperture coupled stacked patch antenna (after S. D. Targonski et al.³² © IEEE 1998)

For further enhancement of the bandwidth, additional resonances are needed that can be introduced by adding more patches. In the stacked configuration the antenna height further increases. A more suitable configuration is to combine the aperture coupled geometry with stacked patches. Such a configuration is shown in Figure 16-24 and investigated in Targonski et al.³² The electromagnetic couplings are between three resonators consisting of a near resonant aperture and two stacked patches. In this design the aperture is coupled to the lower patch, and its size must be selected appropriately to increase the bandwidth through the correct value of the coupling coefficient and the resonance frequencies. The individual coupling between the aperture and the lower patch and that between the patches were investigated by a parametric study of their dimensions. The results are shown in Figure 16-25 to 16-27. The best coupling levels are shown in Figures 16-25*b*, 16-26*b*, and 16-27*b*, along with their dimensional parameters.

Similar studies were also conducted for the substrate thicknesses of the first and second layers and are shown in Figure 16-28 and Figure 16-29. These results show the interrelationship between the coupling of the resonators and the dimensional parameters that can be used to arrive at a desirable design solution, discussed in detail in Targonski et al.³² An example design was then selected to maximize the bandwidth. Its computed and measured return loss and gain are shown in Figures 16-30 and 16-31, which also show the antenna design data. The computed and measured bandwidths were 67 percent (5.05–10.1 GHz) and 69 percent (5.07–10.38 GHz). Considering the complexity of the antenna geometry, the agreement between the computed and measured results is satisfactory. Over most of the band, the gain is above 7 dBi and drops rapidly near the band edges. The computed front-to-back ratio ranged from 8 to 14 dB over most of the band.

Multiple resonances can also be established in dual-layer patch antennas by using multiple planar patches on the second layer.²⁶ The geometry of such an antenna is shown in Figure 16-32, where a single rectangular patch is placed on the lower substrate. On the upper substrate four rectangular patches are etched, such that when symmetrically located on the lower patch, they overlap at the corners.

Patch elements: $PL_1 = 10.8$ mm, $W_1 = 20$ mm, $N_1 = 2$, $PL_2 = 11.2$ mm, $PW_2 = 20$ mm, $N_2 = 3$ (after S. D. Targonski et al³² © IEEE 1998).

FIGURE 16-31 Computed and measured gain for aperture coupled stacked patch antenna. Antenna parameters are mentioned in Figure 16-30 (after S. D. Targonski et al.³² © IEEE 1998).

The degree of coupling between the lower patch and the upper patches is controlled by the amount of the overlap area, as well as by the spacing between the lower and the upper patches. The latter condition is similar to dual stacked patches, where a low permittivity foam substrate is used to separate the two patches. The level of coupling between the lower and one of the upper patches is small, but the combined coupling levels become sufficient to reach the critical coupling coefficient needed for the broadband input impedance. For the configuration of

FIGURE 16-32 Geometry of the stacked microstrip antenna consisting of electromagnetically coupled four patches to a driven patch (after H. Legay and L. Shafai²⁶ © IEE 1994)

FIGURE 16-33 Radiation patterns for the antenna in Figure 16-32 at 4.3 GHz: (a) Directivity. (b) Measurement. Substrate parameters: $\epsilon_{r1} = \epsilon_{r2} = 2.55$, $h_1 = h_2 = 1.58$ mm. Upper patches: $L_1 = 20$ mm, $W_1 = 16$ mm. $S_X = S_Y = 16$ mm. Lower patch: $L_2 = 21.3$ mm, $W_2 = 20$ mm (after H. Legay and L. Shafai²⁶ © IEE 1994).

Figure 16-32 the computed and measured impedance bandwidths were 20 percent. One added benefit of this configuration is its high gain of about 12 dBi. In fact, the original antenna in Legay and Shafai²⁶ was designed to provide high gain without an array. In microstrip arrays the feed network losses deteriorate its performance in sidelobes, cross polarization, gain, and the noise temperature. In the configuration of Figure 16-32, the entire feed network is eliminated to remove its detrimental effect. This stacked configuration was designed as a high gain element for a thinned active microstrip array. Its high gain and wide bandwidth allowed considerable simplification in the feed network of a large array, with improved efficiency and electrical performance. Its measured gain is shown in Figure 16-33.

Further increase in the bandwidth can be obtained by adjusting the spacing between the lower patch and upper patches. In this case, the level of coupling depends on the corner overlaps as well as the spacing. In the bandwidth optimization the two parameters must be adjusted simultaneously to maintain the needed coupling levels. Bandwidths in excess of 45 percent have been obtained. The antenna gain was found to be high for large overlaps and lower interlayer spacing. It is decreased by reducing the overlap or increasing the second substrate height. It was found that the radiation from the lower patch was out of phase with those of the upper patches, and that it tends to reduce their radiation intensity, and thus the antenna gain. Any means of reducing its radiation tends to improve the gain. Increasing the overlap or reducing the interlayer spacing results in covering the central patch and thus reducing its radiation.

16.7 MICROSTRIP ANTENNAS WITH L-SHAPED PROBE

Coaxial probe feeding is attractive in many practical applications, especially in single antennas, because of its simplicity and ease of fabrication. However, wide impedance bandwidths are obtained only by using stacked patches, and the probe height is usually too small to be resonant. Longer probes become too inductive and also radiate in the dipole mode, which is in cross polarization. Thus with longer probes the antenna must become capacitive to compensate for the probe inductance. These properties were generated by a bent *L*-shaped probe,^{33,34} shown in Figure 16-34. A long probe is used as a feed and is bent below the patch. The horizontal section of the probe couples capacitively to the patch and compensates for its inductance. In this manner a resonant probe length can be selected to couple to the patch and increase its bandwidth. With a rectangular patch a parametric study was carried out to investigate its bandwidth and gain. The results are shown in Figure 16-35. Bandwidths in the order of 36 percent, centered at 4.5 GHz, are obtained. The copolar gain is frequency dependent, but remains high over most of the band. It drops rapidly near edges of the band. For better antenna performance the vertical section of the probe must fall slightly outside the patch, i.e., $S < 0$. The radiation patterns are

$$W_x \times W_y = 30 \times 25 \text{ mm}^2, R = 0.5 \text{ mm}$$

shown in Figure 16-36. The copolar patterns have nearly symmetric shape, but the cross polarization is asymmetric and increases near the band edges, causing the gain loss. In the region between 15° and 30° , off the main beam, it increases to around -15 dB.

The performance of the antenna with an *L*-shaped probe over cylindrical and conical grounds was also investigated.³⁵ The bandwidth improved to about 48 percent (2.01 to 3.2 GHz), and peak gain increased to 8.6 dBi. The cross polarization remained high at about -14.2 dB in the *H*-plane. The *L*-shaped probe was similarly investigated with circular and triangular patch

FIGURE 16-36 Radiation patterns of the antenna using parameters in set 2 of Table 16-1 at 4.53 GHz (after C. L. Mak et al.³³ © IEEE 2000)

antennas,³⁶ and similar performances were obtained. In lieu of an L -shaped probe, the T -shaped probe has also been investigated.³⁷ Its performance in bandwidth, gain, and cross polarization was found to be similar to the L -shaped probe. However, adding a second T -shaped probe, symmetrically under the patch, reduced the cross polarization to below -20 dB.

16.8 SLOTTED WIDEBAND PATCH ANTENNAS

In aperture coupled patch antennas, the coupling between a near resonant slot and the patch broadened the bandwidth to about 30 percent or higher. Another location for the slot is the patch surface. However, since the slot is long, the patch must be wide and the slot must be bent but remain symmetrical on the patch. Using this concept a U -shaped slotted patch was experimentally investigated in Huynh and Lee,³⁸ and an impedance bandwidth of 47 percent, from 0.812 to 1.282 GHz, was obtained. Later, the same configuration was investigated numerically.³⁹ It was found that within the impedance band the antenna polarization changes at the upper frequencies. The realistic bandwidth, for the same polarization, was found to be about 30 percent. Even then the cross polarization was increased significantly near the end of its impedance band.^{39,40} Figure 16-37 shows the geometry of this antenna and its dimensional parameters. The slotted patch is over a thick foam substrate, and a coaxial probe is used to feed it at the patch center. Figure 16-38a shows its return loss plot, and Figure 16-38b the gain at two orthogonal polarizations. It is clear that the antenna polarization starts switching around 1 GHz.

Attempts were also made to design this antenna on a dielectric substrate $\epsilon_r > 1$. However, these initial attempts were not too successful, and impedance bandwidths were limited to around 20 percent. Instead, numerous authors have investigated successfully the same and derivatives of this antenna. In Bhalla and Shafai⁴¹ approximate expressions for minimum return loss frequencies of the U -slot antenna were proposed and investigated. They are given in Eqs. 16-6 and 16-7:

$$f_1 = \frac{c}{\left(\frac{W_s}{2} + W + \frac{3}{2} \Delta W - \frac{b}{2} \right) \sqrt{\epsilon_{eff}}} \quad (16-6)$$

$$f_1 = \frac{c}{\left(\frac{L}{2} + W + \frac{3}{2} \Delta W - \frac{W_s}{4} + F - a \frac{b}{2} + \frac{t}{2} \right) \sqrt{\epsilon_{eff}}} \quad (16-7)$$

FIGURE 16-37 Geometry of coaxially fed rectangular patch with a U -shaped slot: (a) top view and (b) side view (after R. Bhalla and L. Shafai⁴¹ © *Microwave and Optical Technology Letters* 2002)

Dimensions of the antenna in centimeters: $W = 12.45$, $L = 21.97$, $W_s = 6.86$, $L_s = 8.22$, $a = 2.29$, $b = 1.94$, $t = 1.02$, $h = 2.69$, $F = W/2$ (after T. Huynh and K. F. Lee³⁸ © *Electronics Letters* 1995). (b) Maximum gain of x- and y-polarizations of the U-slot antenna.³⁹

where c is the velocity of light in free space and ΔW is the fringing effect calculated from

$$\Delta W = 0.412h \frac{(\epsilon_{eff} + 0.3) \left(\frac{L}{h} + 0.264 \right)}{(\epsilon_{eff} - 0.258) \left(\frac{L}{h} + 0.8 \right)} \quad (16-8)$$

and ϵ_e is the effective permittivity calculated from

$$\epsilon_{eff} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + \frac{10h}{W} \right)^{-\frac{1}{2}} \quad (16-9)$$

The parameters in these equations are defined in Figure 16-37 and Figures 16-39 through 16-41. The rationale for choosing these equations is based on observation of the

FIGURE 16-39 Return loss of the microstrip antenna with a single U-shaped slot:⁴¹ $L = 37.5$ mm, $W = 26$ mm, $L_s = 19.5$ mm, $W_s = 12$ mm, $a = 3.7$ mm, $b = 2.8$ mm, $t = 2.1$ mm, foam height $h = 5$ mm. ----- $F = 14.50$ mm, ——— $F = 15.0$ mm, -.-.- $F = 15.5$ mm.

FIGURE 16-40 Surface-current distribution on microstrip patch at $f_1 = 4.12$ GHz (a) and (b) surface-current line on the patch at $f_1 = 4.12$ GHz. Here $F = 15.0$ mm. Other dimensions are the same as in Figure 16-39 (after R. Bhalla and L. Shafai⁴¹ © *Microwave and Optical Technology Letters* 2002).

patch current distributions at the null frequencies f_1 and f_2 , shown in Figure 16-40 and Figure 16-41. At f_1 , currents appear to start at the center point behind the slot and terminate at the opposite edge. These currents resemble the patch current distribution due to the TM_{11} mode. Thus, the length of the average current path will be half wavelength. At the second null the currents appear to start at the feed point and end at the center point behind the slot. This length is one wavelength at f_2 . These equations may be used for calculating approximately the null frequencies that can be used in determining the initial antenna dimensional parameters. However, since the substrate height is not present in these equations, they will only provide the patch and slot parameters.

FIGURE 16-41 Surface-current distribution on microstrip patch at $f_2 = 5.08$ GHz (a) and (b) surface-current line on the patch at $f_2 = 5.08$ GHz. Here $F = 15.0$ mm. Other dimensions are the same as in Figure 16-39 (after R. Bhalla and L. Shafai⁴¹ © *Microwave and Optical Technology Letters* 2002).

FIGURE 16-42 Geometry of the microstrip patch antenna with a circular arc slot (after R. Bhalla and L. Shafai⁴² © IEEE 2002)

A rectangular patch with a circular slot was also studied and designed.⁴² It provided a bandwidth of 31.1 percent, at a center frequency of about 4 GHz. Its geometry with dimensional parameters is shown in Figure 16-42. The return loss plot is shown in Figure 16-43. Again, approximate expressions for the return loss null frequencies were developed and are given next.

$$f_1 = \frac{c}{2 \left(R_1 + (W + 2\Delta W) - \frac{(\Delta W + d)}{2} \right) \sqrt{\epsilon_{eff}}} \quad (16-10)$$

FIGURE 16-43 Return loss of the microstrip patch antenna with a circular arc slot, shown in Figure 16-42: $L = 55.5$ mm, $W = 29$ mm, $(x_c, y_c) = (0$ mm, -2.5 mm), $(a_1, b_1) = (5$ mm, 2.5 mm), $(a_2, b_2) = (7$ mm, 5.5 mm), $t = 2.83$ mm, $d = 1.37$ mm, $F = 16$ mm, foam substrate height = 5.5 mm (after R. Bhalla and L. Shafai⁴² © IEEE 2002).

$$f_2 = \frac{c}{\left(\frac{L}{2} + \frac{W}{2} + \frac{3}{2}\Delta W + \frac{R_2}{2} + F - \frac{d}{2}\right)\sqrt{\epsilon_{eff}}} \quad (16-11)$$

These equations were also developed using the current distributions at the null frequencies and found to be accurate within 4 percent.

A more elaborate, but approximate, design approach for a U -slotted rectangular patch is developed in Weigand et al⁴³ based on a detailed numerical investigation. They have defined four resonant frequencies: f_{res1} , f_{res2} , f_{res3} , and f_{res4} . They are related to the slot resonance, the TM_{01} mode of the patch, the antenna center frequency, and the slot resonance frequency in free space. The first resonance frequency is not radiating efficiently and is discarded. The second, third, and fourth resonant frequencies are related to the antenna dimensional parameters and the substrate relative permittivity. Based on these, a design approach is developed that, although approximate, helps in determining the initial design of the antenna. A final tuning may be necessary to yield the desired antenna. An important feature of this study is the fact that it includes the substrate permittivity in the design, and a wideband antenna on a dielectric substrate with $\epsilon_r = 2.2$ is designed that provides a bandwidth of 39 percent, between 4.21 and 6.26 GHz. Figure 16-44 defines the antenna dimensional parameters, and the approximate equations for the last three resonance frequencies are given by

$$f_{res2} \approx \frac{c}{2\sqrt{\epsilon_{eff}}\left(B + 2\Delta B + \frac{D}{2} - E\right)} \quad (16-12)$$

$$f_{res3} \approx \frac{c}{2\sqrt{\epsilon_{eff}}(B + 2\Delta B)} \quad (16-13)$$

$$f_{res4} \approx \frac{c}{(2C + D) + \sqrt{\epsilon_{eff(pp)}}(B - E - H + 2\Delta_{B-E-H})} \quad (16-14)$$

where ΔB and Δ_{B-E-H} are the fringing effect at the patch edge and the slot, respectively. Based on these equations, a design procedure is developed, which is described next.

1. Specify the center frequency and 2:1 VSWR bandwidth of the desired antenna. Approximate the center frequency as f_{res3} and the lower and upper frequency bounds of the bandwidth as f_{res2} and f_{res4} , respectively.
2. Select a substrate permittivity ϵ_r and a substrate thickness T . There is a lower limit on T below which broadband operation is unlikely. Therefore, the substrate thickness and permittivity should satisfy the following rule of thumb derived from the existing literature and parametric studies:

$$T \geq 0.06 \frac{\lambda_{res3}(\text{air})}{\sqrt{\epsilon_r}}$$

3. Estimate the quantity $B + 2\Delta B$ as follows:

$$B + 2\Delta B \approx \frac{c}{2\sqrt{\epsilon_r}f_{res3}}$$

FIGURE 16-44 Geometry of the rectangular *U*-slot microstrip patch antenna (after S. Weigand et al⁴³ © IEEE 2003): Dimensions and material properties of the initial *U*-slot antenna used in the parametric studies (after S. Weigand et al⁴³ © IEEE 2003):

<i>A</i> (mm)	<i>B</i> (mm)	<i>C</i> (mm)	<i>D</i> (mm)	<i>E</i> (mm)	<i>F</i> (mm)	<i>H</i> (mm)	<i>R</i> (mm)	<i>T</i> (mm)	Offset (mm)	ϵ_r
36.0	26.0	12.0	16.0	2.0	2.0	4.0	0.5	5.0	0.0	2.20

4. Calculate *A* as

$$A = 1.5(B + 2\Delta B)$$

5. Calculate ϵ_{eff} and $2\Delta B$ using the following common equations:

$$\epsilon_{eff} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + \frac{12T}{A} \right)^{-1/2}$$

$$2\Delta B = 0.824T \frac{(\epsilon_{eff} + 0.3) \left(\frac{A}{T} + 0.262 \right)}{(\epsilon_{eff} - 0.258) \left(\frac{A}{T} + 0.813 \right)}$$

6. Back calculate the value of B :

$$B = \frac{c}{2\sqrt{\epsilon_{eff}} f_{res3}} - 2\Delta B$$

7. Select a starting value of slot thickness using the following rule of thumb:

$$E = F = \frac{\lambda_{res3}(\text{air})}{60}$$

8. Calculate D by solving Eq. 16-12:

$$D = \frac{c}{\sqrt{\epsilon_{eff}} f_{res2}} - 2(B + 2\Delta B - E)$$

9. Select C such that

$$\frac{C}{A} \geq 0.3 \quad \text{and} \quad \frac{C}{D} \geq 0.75$$

10. Calculate the effective permittivity and effective length extension of the pseudo patch of the fourth resonance with the effective width as $D - 2F$:

$$\epsilon_{eff(pp)} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + \frac{12T}{D - 2F} \right)^{-1/2}$$

$$2\Delta_{B-E-F} = 0.824T \frac{(\epsilon_{eff(pp)} + 0.3) \left(\frac{D - 2F}{T} + 0.262 \right)}{(\epsilon_{eff(pp)} - 0.258) \left(\frac{D - 2F}{T} + 0.813 \right)}$$

11. Calculate H by solving Eq. 16-14:

$$H \approx B - E + 2\Delta_{B-E-H} - \frac{1}{\sqrt{\epsilon_{eff(pp)}}} \left(\frac{c}{f_{res4}} - (2C + D) \right)$$

12. Check that the sum $C + E + H$ is less than B . If not, adjust C by changing the ratios in step 9 and the value of H until the design is physically realizable.

16.9 VARIATIONS OF U-SLOT PATCH ANTENNA

Edge-Slotted v-Slot Antenna: The V-slot antenna was studied in Rafi and Shafai,⁴⁴ which showed that the V angle can be used to improve its performance. The bandwidth of a U -slot

FIGURE 16-45 Geometries of wideband V-slotted microstrip patch antennas with two parallel-edge slots of different configurations: $\epsilon_r = 1.05$, $h = 5.5$ mm, $L_G = W_G = 60$ mm, $L = 26$ mm, $W = 36$ mm, $\theta = 10^\circ$, $L_V = 2.7$ mm, $W_V = 8.8$ mm, $t = 2$ mm, $d = 2.3$ mm, $L_p = 22$ mm, $t_p = 1.5$ mm, $d_p = 3$ mm⁴⁵

antenna was increased from about 30 percent to 36.5 percent by replacing the U -slot with a V -slot. The V angle is quite small and around 10° . A major problem with both U -slot and V -slot antennas is the cross polarization in the H -plane that increases rapidly at high frequencies. This problem was investigated and resolved in Rafi and Shafai.⁴⁵ Two additional slots were incorporated at the edge of the patch, as shown in Figure 16-45, which shows three different possibilities. Their return loss plots are shown in Figure 16-46. Antenna I shows a wideband performance similar to the original V -slot antenna without the edge slots. The cross polarizations in the H -plane are shown in Figure 16-47. For the original antenna, it increases rapidly beyond 5 GHz. However, for Antenna I, which has edge slots open at the top, the cross polarization is low and nearly independent of frequency. To investigate the effect of this cross-polarization improvement, its gain performance is compared with the original antenna in Figure 16-48. It is clear that the gain of the edge slotted antenna has increased by as much as 3 dB at high frequencies. This indicates that the radiated power of the cross-polar component has returned to the copolar component. Figure 16-49 shows the principal plane radiation patterns of the original and edge slotted Antenna I. The improvements in gain and cross polarization are evident.

Circular-Arc V-Slot Antenna: The patch shape in this antenna is changed from a rectangle to a double arc, as shown in Figure 16-50.⁴⁶ The bandwidth of this new antenna is increased to 40 percent, from 30 percent of the *U*-slot antenna. Other parameters remain similar.

Diamond-Shaped V-Slot Antenna: The patch in this antenna is diamond shaped, as shown in Figure 16-51.⁴⁷ Its return-loss plot in Figure 16-52 and the input impedance in Figure 16-53 show that there is an additional resonance, and the bandwidth increases to 50 percent.

Double U-Slot Antenna: In this antenna a second U-slot is placed inside the first one⁴⁸ (see Figure 16-54). Its bandwidth has increased to 44 percent (1.24–1.95 GHz), as shown in Figure 16-55. The new resonance is evident from the second loop on the Smith Chart of Figure 16-56.

Circular Patch L-Probe Antenna: An L-probe is used to feed a circular patch with a circular-slot, as shown in Figure 16-57.⁴⁹ Its bandwidth is 40 percent, from 3.55 to 5.32 GHz, as shown in Figure 16-58. Within the bandwidth, its gain was above 8 dBi.

FIGURE 16-54 Geometry of double U-slot patch antenna on a foam substrate (Y. X. Guo et al⁴⁸ © *Electronics Letters* 1998)

FIGURE 16-55 SWR against frequency of the antenna with double U -slot in Figure 16-54 (Y. X. Guo et al⁴⁸ © *Electronics Letters* 1998)

Stacked slotted antennas have also been investigated for achieving even larger bandwidths. In Clénet et al⁵⁰ a U -slotted patch is stacked with a conventional patch, and bandwidth of 45 percent is obtained. In Rafi and Shafai⁵¹ two U -slotted patches are stacked and investigated (see Figure 16-59). An impedance bandwidth of 46 percent is obtained. In Rafi and Shafai⁵² a V -slotted patch antenna is first stacked with a conventional patch (see Figure 16-60) and obtained a bandwidth of 47 percent. Then it is stacked with another V -slotted patch (see Figure 16-61). The bandwidth of the new antenna was increased to 54 percent.

16.10 EBG LOADED SLOTTED PATCH ANTENNAS

Electromagnetic band gap structures interact strongly with the substrate field and have been used to reduce surface wave excitation and losses in microstrip antennas. In this case an attempt was made to use them for further increasing the patch bandwidth. The results have been surprisingly good. In Rafi and Shafai⁵³ small shorted patches were placed parallel to the antenna radiating edges to intercept the substrate mode fields. They generate a high impedance barrier to the substrate fields and reradiate their power, improving the bandwidth and gain. The resulting antenna geometry is shown in Figure 16-62, and its return

loss in Figure 16-63. An impedance bandwidth of 58 percent was obtained. This is significant, since it is obtained with a single-layer design. Its radiation characteristics remained similar to the original antenna.

A similar approach was also used for loading a slotted-diamond patch antenna.⁵⁴ The loading EBG structures, however, were two periodically shorted narrow patches, in lieu of arrays of small EBG patches. The antenna geometry is shown in Figure 16-64. The VSWR plots for both rectangular and diamond-shaped patches are shown in Figure 16-65. The achieved bandwidth of the latter antenna was 66 percent, much higher than that of

even stacked patches. Figure 16-66 shows the gains and cross polarizations. The gain of the loaded antenna is enhanced, especially at high frequencies, making it independent of frequency. Because in slotted patch antennas the gain decreases rapidly at high frequencies, the improvement in the gain is also remarkable. The midband radiation patterns are shown in Figure 16-67.

16.11 MICROSTRIP PATCH ANTENNAS WITH EBG SUBSTRATE

In microstrip patch and other low-profile antennas over a conducting ground plane, the negative image of the radiating electric current detrimentally influences its radiation efficiency and bandwidth. In contrast, a magnetic ground plane would enhance the radiation, and thus the efficiency and bandwidth. However, since a perfect magnetic ground plane does not exist, it should be developed using periodic materials such as EBG structures, which have finite band gaps. As a result, the bandwidth of a so-generated magnetic ground plane will also be finite, and restricted to its band gap, outside which it will have a complex surface impedance similar to tuned circuits. In this section the properties of a microstrip patch antenna over a high-impedance EBG substrate is investigated within its band gap.

The geometry of the antenna is shown in Figure 16-68. A rectangular patch antenna is placed over a high-impedance EBG whose band gap occurs within a frequency band of 5.8–7.5 GHz.⁵⁵ A reference patch antenna, i.e., the same rectangular patch over a dielectric substrate of similar thickness (1.59 mm) and size with a perfect electric ground plane, was also designed for operation at 6.6 GHz.

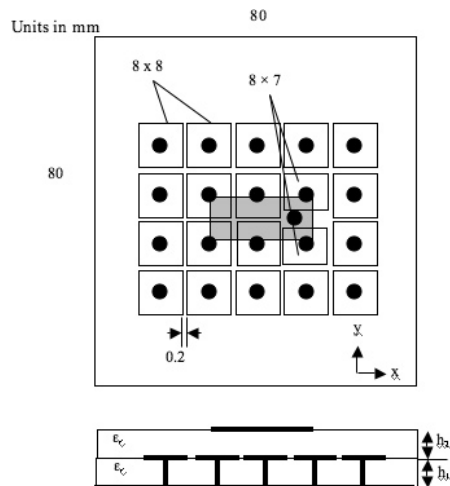

FIGURE 16-68 Geometry of a microstrip patch with an EBG substrate, patch length $L = 14$ mm, width $W = 6$ mm, $\epsilon_r = 2.5$, $h_1 = h_2 = 1.59$ mm, feed distance from patch center $L_f = 5.2$ mm (after D. Qu et al⁵⁵ © IEE 2006)

TABLE 16-2 Minimum S_{11} , Bandwidth, and Gain for the Antenna in Figure 16-68 vs. the Feed Location L_f

Feed Location L_f (mm)	Minimum S_{11} (dB)	Impedance Bandwidth	Gain at $\theta = 0^\circ$ (dBi)
4.6	-22.44	19.91% (6.24–7.62 GHz)	10.31
5.2	-44.77	20.20% (6.23–7.63 GHz)	10.32
5.8	-35.75	16.38% (6.50–7.66 GHz)	10.32

Because of the small size of the ground plane (80 mm \times 80 mm), its performance in gain was poor and provided a boresight gain of only 3.92 dBi. Its bandwidth was also small and about 3.85 percent. The microstrip patch over the EBG substrate was also designed for 6.6 GHz and had the parameters Length $L = 14$ mm, Width $W = 6$ mm, $\epsilon_r = 2.5$, $\tan \delta = 0.001$, substrate heights $h_1 = h_2 = 1.59$ mm, and probe distance from the patch center $L_f = 5.2$ mm. The two central EBG patches are 8 mm \times 7 mm, to accommodate the feed probe. Other EBG patches are 8 mm \times 8 mm, with a spacing of 0.2 mm. The ground plane size is 80 mm \times 80 mm.

A parametric study was conducted for this antenna. First, the feed location L_f was assigned different values. Its effects, which are significant, on the patch minimum S_{11} , bandwidth, and gain are shown in Table 16-2. When $L_f = 5.2$ mm, the impedance bandwidth reaches 20.20 percent (6.23–7.63 GHz), and minimum S_{11} is -44.77 dB. The gain is not sensitive to the feed location, and its maximum of 10.32 dBi is obtained for this feed location, as the mismatch loss is minimal. The gain bandwidth was larger than its impedance bandwidth and remained within 1.0 dB of its peak in about 15 percent bandwidth. Next, the effect of patch width was studied. The results are shown in Table 16-3, again showing significant effects on the impedance bandwidth. The gain bandwidth was large similar to the previous case.

For this antenna, with $W = 6$ mm, $L_f = 5.2$ mm, effects of different ground plane sizes were also studied. The results are shown in Table 16-4, indicating a relatively minor effect on the patch bandwidth. The selected ground plane sizes are around 1 to 1.5 wavelengths, where the patch gain and bandwidth remained nearly constant, larger than that of the impedance bandwidth. The gain and its bandwidth remained large, as long as the ground plane size was larger than one-half wavelength.

TABLE 16-3 Minimum S_{11} , Bandwidth, and Gain for the Antenna of Figure 16-68 vs. the Patch Width

Patch Width (mm)	Minimum S_{11} (dB)	Impedance Bandwidth	Gain at $\theta = 0^\circ$ (dBi)
5.5	-33.93	16.12% (6.50–7.64 GHz)	10.34
6.0	-44.77	20.20% (6.23–7.63 GHz)	10.32
6.5	-23.42	16.34% (6.35–7.48 GHz)	10.32

TABLE 16-4 Minimum S_{11} , Bandwidth, and Gain for the Antenna of Figure 16-68 vs. Its Ground Plane Size

Ground Plane Size $L \times W$ (mm)	Minimum S_{11} (dB)	Impedance Bandwidth	Gain at $\theta = 0^\circ$ (dBi)
55×55	-29.75	18.64% (6.42–7.74 GHz)	10.20
65×65	-26.62	18.13% (6.42–7.70 GHz)	10.39
80×80	-44.77	20.20% (6.23–7.63 GHz)	10.32

TABLE 16-5 Minimum S_{11} , Bandwidth, and Gain for the Antenna of Figure 16-68 vs. the EBG Spacing

EBG Spacing (mm)	Minimum S_{11} (dB)	Impedance Bandwidth	Gain at $\theta = 0^\circ$ (dBi)
0.1	-34.42	17.97% (6.23–7.46 GHz)	9.67
0.2	-44.77	20.20% (6.23–7.63 GHz)	10.32
0.3	-22.41	21.08% (6.24–7.71 GHz)	9.81

For the antenna with $80 \text{ mm} \times 80 \text{ mm}$ ground plane, the effect of EBG patch spacing was studied next. The results are shown in Table 16-5, affecting all antenna parameters. The impedance bandwidth is broadest (21.08 percent) when the EBG spacing is 0.3 mm. Its S_{11} plot is shown in Figure 16-69.

The radiation patterns of the antenna of Figure 16-68 with the EBG substrate are shown in Figures 16-70a and 16-70b, at 6.26 GHz. The maximum gain is 9.81 dBi at $\theta = 0^\circ$, which is much higher than that of the reference patch (3.92 dBi). The H -plane cross polarization has a peak level of -21 dB.

The results in this study showed that a microstrip patch antenna over an EBG ground plane and within its band gap has a significantly improved performance in its impedance bandwidth, gain, and cross polarization. In addition, the patch gain was relatively insensitive to its parameters and remained high within its impedance bandwidth. The improvements in gain and bandwidth are expected from antennas over a magnetic ground plane, and the selected EBG substrate behaves similarly within its band gap.

17.1 INTRODUCTION

History of Dielectric Resonator Antennas

The term *dielectric resonator* (DR) first appeared in 1939, when Ritchmyer¹ of Stanford University showed that unmetallized dielectric objects in the form of *toroids* could function as microwave resonators. However, his theoretical investigations failed to generate significant interest and practically nothing happened in this area for over 25 years. In the early 1960s, researchers from Columbia University, Okaya and Barash,^{2,3} reported the first ever DR in the form of a single crystal TiO_2 . In the mid-1960s, Cohn⁴ and his coworkers at Rantec Corporation performed the first extensive theoretical and experimental evaluation of DR. Nevertheless, the DR was still far from being used in practical applications. A real breakthrough in the dielectric ceramic industry occurred in the early 1970s when Masse et al developed the first temperature-stable, low-loss barium tetratitanate ceramics.⁵ In 1975, Van Bladel⁶ reported detailed theory to evaluate the modes of DR. The emergence of DR as a circuit element for several microwave wireless devices has injected tremendous interest into the research of such material.⁷⁻⁹ With the development of low-loss dielectrics, resonators with high Q elements for circuit applications such as filters and oscillators were developed, thus increasing the possibilities for developing more compact integrated microwave circuits.⁸ For these circuits, resonators, which are typically cylindrical in shape, are made out of high dielectric constant materials ($\epsilon_r > 35$) and are usually shielded to maintain the high quality factor needed for applications in oscillators, filters, etc.

DRs of different shapes have various modes of oscillation. With the proper excitation of certain modes and with no shielding, these resonators can actually become efficient radiators instead of energy storage devices. This concept led to the exploration of DRs as antennas. Although open DRs were found to radiate many years ago,^{10,11} the idea of using DR as a practical antenna materialized in 1983, when Long et al¹² published a paper on cylindrical dielectric resonator antennas (DRAs). Subsequently, other researchers investigated rectangular¹³ and hemispherical¹⁴ DRAs. These works laid the foundation for later extensive investigations on various aspects of DRAs. Considerable work done on analyzing their resonant modes, radiation characteristics, and various feeding schemes has demonstrated that these “new” radiators could offer new and attractive features in antenna design. Many new elements and arrays with attractive characteristics for wireless and other applications have been implemented and descriptions of some of these are included in the literature.¹⁵⁻¹⁷

Advantages of DRAs

As has been recently demonstrated, DRAs offer a high degree of flexibility and versatility over a wide frequency range, allowing for designers to suit many requirements. DRAs offer the following advantages:

- The DRA size is proportional to $\lambda_o/\epsilon_r^{1/2}$, where λ_o is the wavelength at resonant frequency and ϵ_r is the dielectric constant of the DR. Thus for the same frequency there is a natural reduction in size, compared with their conventional counterparts like microstrip antennas. Also, different values of ϵ_r (ranging from 4 to 100) can be used, thus allowing the designer the flexibility in controlling the size and bandwidth.
- Depending on the resonator shape, various modes can be excited within the DRA element. These modes can produce different radiation patterns for various coverage requirements. Also, the Q -factor of some of these modes will depend on the aspect ratio of the DRA, thus allowing one more degree of flexibility in the design.

- Many of the existing feeding schemes can be used (slots, probes, microstrip, coplanar waveguides, dielectric image guide, etc.). This makes them easy to integrate with existing technologies.
- Compared with the microstrip antenna, DRA has a much wider impedance bandwidth. This is because the microstrip antenna radiates only through two narrow radiation slots, whereas the DRA radiates through the whole antenna surface except the grounded part. Moreover the operating bandwidth of a DRA can be varied by suitably choosing the dielectric constant of the resonator material and its dimensions.
- DRAs have been designed to operate over a wide frequency range (1 GHz to 44 GHz) compared with other antennas existing in the literature.
- DRAs have a high dielectric strength and hence higher power handling capacity. Moreover the temperature-stable ceramics enable the antenna to operate in a wide temperature range.

Fundamental Modes and Their Radiation Mechanisms

A microwave resonator has an infinite number of resonant modes, each corresponding to a particular resonant frequency at which the stored electric energy is equal to the magnetic energy. To simplify the discussion, we use the cylindrical resonator as our reference in the free space. Based on that, the excited modes can be classified into three distinct types: *TE*, *TM*, and hybrid. The fields for *TE* and *TM* modes are axisymmetric, whereas hybrid modes are azimuthally dependent. According to the mode nomenclature described by Kobayashi et al.^{18,19} the variation of fields along the azimuthal, radial and Z-direction inside the resonator is denoted by adding mode indices as subscripts to each family of modes. The *TE*, *TM*, and hybrid modes are classified as $TE_{mnp+\delta}$, $TM_{mnp+\delta}$ and $HE_{mnp+\delta}$ respectively. The first index denotes the number of full-period field variations in azimuthal direction, the index n ($n = 1, 2, 3, \dots$) denotes the order of variation of the field along the radial direction and the index $p + \delta$ ($p = 0, 1, 2, \dots$) denotes the order of variation of the fields along the Z-direction. Here, the third index denotes the fact that the dielectric resonator is shorter than integer multiples of half the dielectric wavelength. The actual value of δ depends on the relative dielectric constant of the resonator and the substrate and on the proximity to the top and bottom conductor planes. An interesting feature of DR is the variation in field distribution of different modes, because the modes behave like electric and magnetic multipoles such as dipole, quadrupole, octupole, etc. The mode nomenclature makes possible the accurate prediction of far-field radiation of dielectric resonators in their application as antennas. For example, the $TE_{01\delta}$ mode radiates like a short magnetic dipole oriented along its axis, whereas its *TM* counterpart radiates like a short electric dipole and the $HE_{11\delta}$ mode radiates like a horizontal magnetic dipole. The modes that are most commonly used for radiating applications are $TE_{01\delta}$, $TM_{01\delta}$, and $HE_{11\delta}$. The corresponding field distributions for cylindrical DRs are shown in Figure 17-1.

The equations for the resonant frequency and radiation *Q*-factor of the $TE_{01\delta}$, $TM_{01\delta}$ and $HE_{11\delta}$ modes of a cylindrical DRA with dielectric constant ϵ_r , radius a , and height h kept above an infinite ground plane and fed by an electromagnetic signal of free space velocity c are given next. These equations have been derived by a combination of dielectric waveguide model and curve fitting ($k_o a$ vs. a/h) based on extensive numerical and experimental investigations.^{15,20}

$TE_{01\delta}$ mode:

$$f_o = \frac{2.921c\epsilon_r^{-0.465}}{2\pi a} [0.691 + 0.319x - 0.035x^2] \quad (17-1)$$

$$Q = 0.012\epsilon_r^{1.2076} [5.270x + 1106.188x^{0.625} e^{-1.0272x}] \quad (17-2)$$

FIGURE 17-1 Sketch for the field distributions of the first three common modes

where $x = a/2h$. The ideal radiation pattern of $TE_{01\delta}$ mode is as shown in Figure 17-2, if the DR is split along its axis and placed on a ground plane.

$TM_{01\delta}$ mode:

$$f_o = \frac{2.933c\epsilon_r^{-0.468}}{2\pi a} \{1 - [0.075 - 0.05x](\epsilon_r - 10)/28\} \{1.048 + 0.377x - 0.071x^2\} \quad (17-3)$$

$$Q = 0.009\epsilon_r^{0.888} e^{0.040\epsilon_r} \{1 - [0.3 - 0.2x](38 - \epsilon_r)/28\} \{9.498x + 2058.33x^{4.322} e^{-3.501x}\} \quad (17-4)$$

The ideal radiation pattern of $TM_{01\delta}$ mode when it is cut to half and placed on a ground plane is depicted in Figure 17-3.

$HE_{11\delta}$ mode:

$$f_o = \frac{2.735c\epsilon_r^{-0.436}}{2\pi a} [0.543 + 0.589x - 0.050x^2] \quad (17-5)$$

$$Q = 0.013\epsilon_r^{1.202} [2.135x + 228.043xe^{-2.046x+0.111x^2}] \quad (17-6)$$

The ideal radiation pattern of $HE_{11\delta}$ mode when it is cut to half and placed on a ground plane is illustrated in Figure 17-4.

FIGURE 17-2 Ideal radiation pattern of $TE_{01\delta}$ mode

FIGURE 17-3 Ideal radiation pattern of $TM_{01\delta}$ mode

The resonant frequencies and radiation of ideal modes for other geometries can be obtained with some approximations or with complete numerical eigenvalue solutions. The exception are hemispherical shapes for which modes can be obtained exactly by enforcing the boundary conditions on the surface of the sphere to obtain a characteristic (eigenvalue) equation from which numerical solutions can be obtained to get the resonant frequencies.

Excitation Techniques of DRAs

The operational mode of a DRA depends on the method of excitation employed. Moreover, the coupling mechanisms significantly affect the resonant frequency and radiation Q -factor of a DRA. A number of excitation techniques have been adopted. These include coaxial probe,^{21,22} aperture coupling with a microstrip feedline,^{23,24} aperture coupling with a coaxial feedline,^{25,26} waveguide coupled aperture,^{27,28} direct microstrip feedline,^{29,30} coplanar feed,³¹ soldered through probe,³² slot line,³³ conformal strip³⁴ and direct image guide.³⁵ Some of these excitation methods are illustrated in Figure 17-5.

In aperture coupling methods, the aperture can be of any shape, such as narrow slot, loop, cross, or C -shape cut in the ground plane and can be fed by a microstrip line/coaxial feedline beneath the ground plane or aperture cut on the surface of a waveguide. Here the aperture behaves like a magnetic current running parallel to the length of the slot, which excites the magnetic fields in DRA. In this case moving the DRA with respect to the

FIGURE 17-4 Ideal radiation pattern of $HE_{11\delta}$ mode

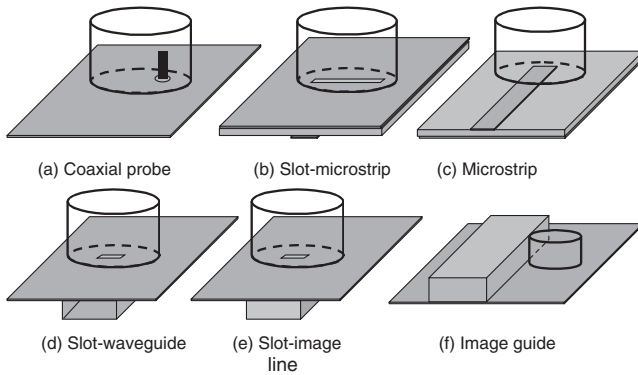

FIGURE 17-5 Different excitation mechanisms for the DRA

aperture or controlling the aperture size can adjust the coupling level. This method has the advantage of feeding networks kept below the ground plane and hence avoids the spurious modes. Moreover, slot aperture coupling is widely used for integrating DRAs with printed feed structures.

The excitation of DRs using coplanar waveguide lines appears to be highly promising because they enable easy coupling with MMICs. In this case, coupling level can be adjusted by positioning the DRA over the coplanar structure. Impedance tuning can be done by adding stubs, slots, or loops at the end of the coplanar line. Though coaxial probes and coplanar loops work alike, the latter has the advantage of unobtrusive and planar structure to benefit integration. By moving the position of DR over the loop, the operational mode can be selected.

Dielectric image guide excitation of DRAs offers advantages over microstrip line methods in that they do not suffer from conductor losses, especially at millimeter wave frequencies. Here the coupling between the guide and the DR is usually small, but can be increased by operating the guide closer to the cutoff frequency. This method is similar to the waveguide slot method, but with the image line replacing the waveguide. These types of excitations find many applications, especially in series fed linear DRA arrays.

In coaxial probe feed excitation, the center pin of a coaxial transmission line is extended through the ground plane. It can also be soldered to a flat metal strip. This can be considered as an electric current running vertical to the DRA height. The probe can either be located adjacent to the DRA or can be embedded within the body. The strength of coupling depends on the length and location of the probe. Various modes can also be excited based on the probe location. The extent of coupling can be adjusted by modifying the probe height. In this method, various modes are excited depending on the position of the probe. Another advantage of this method is that the antenna system can be directly connected to a 50 Ω circuit without the aid of any matching network.

Use of the direct microstrip line mechanism is the simplest method to energize DRAs. In this method, a microstrip line printed on the same substrate excites a DR that could be placed directly over the microstrip line or nearby over the dielectric substrate. The level of coupling can be adjusted by the lateral position of the DR with respect to the microstrip line and by using substrate with different permittivity. For wider bandwidth, ϵ_r of the substrate should be kept low, but requires a reasonable value for better coupling. To have acceptable radiation efficiency, microstrip-line excited DRA arrays are being used. Microstrip line offers the advantage of easy and cost-effective fabrication of DRA arrays because feedlines can be

simply printed over the substrate. But these have the disadvantage that polarization of the array is dictated by the orientation of the microstrip line. Moreover, this excitation scheme may also generate surface waves in the dielectric substrate, which is highly undesirable.

It should be clear that once we use the real source, different modes could be excited and in some cases the radiation patterns could be deformed from the intended mode pattern. Such deformation may be controlled or reduced by adjusting the excitation position or coupling level.

17.2 POSSIBLE METHODS OF ANALYSIS

The approaches to solving DRA problems theoretically can be broadly classified into two: (1) theoretical models like cavity, waveguide, and curve fitting methods and (2) numerical methods based on frequency domain and time domain techniques.

Theoretical Models

Theoretical models are appropriate for conical structures. Then modal analysis and Green's functions can be derived getting analytical expressions.

Cavity Model (Cylindrical DRA) Cavity model¹² is the first and simplest analysis technique applied to a DRA. As an approximation, the DRA can be considered as a dielectric cavity with the surfaces as perfect magnetic conductors. In that case, the *TE* and *TM* modes are the only modes possible. This model is used to compute the resonant frequency and the radiation patterns. Because of this approximation, high error is expected in predicting the resonant frequency.

Dielectric Wave-Guide Model (Rectangular DRA) This method was first employed³⁶⁻³⁸ to analyze the resonant frequency and radiation fields of a rectangular DRA. Consider a rectangular DRA of length l , width w , and height h , mounted on an infinite ground plane. Typically the $TE_{11\delta}^z$ mode will be the prominent one excited, for $l, w > h$. As an approximation the top surface and two sidewalls (mostly in the propagation direction) assume perfect magnetic boundaries, whereas the other two sidewalls assume imperfect magnetic walls and the bottom surface that is in contact with the ground plane acts as an electric wall. With this, the electric and magnetic components of the field in the DRA can be expressed as

$$H_x = \frac{(k_x k_z)}{j\omega\mu_0} \sin(k_x x) \cos(k_y y) \sin(k_z z) \quad (17-7)$$

$$H_y = \frac{(k_y k_z)}{j\omega\mu_0} \cos(k_x x) \sin(k_y y) \sin(k_z z) \quad (17-8)$$

$$H_z = \frac{(k_x^2 + k_y^2)}{j\omega\mu_0} \cos(k_x x) \cos(k_y y) \cos(k_z z) \quad (17-9)$$

$$E_x = k_y \cos(k_x x) \sin(k_y y) \cos(k_z z) \quad (17-10)$$

$$E_y = -k_x \sin(k_x x) \cos(k_y y) \cos(k_z z) \quad (17-11)$$

$$E_z = 0 \quad (17-12)$$

where

$$k_x^2 + k_y^2 + k_z^2 = \epsilon_r k_o^2, \quad k_z \tan(k_z l/2) = \sqrt{(\epsilon - 1)k_o^2 - k_z^2} \quad (17-13)$$

$$k_o = \frac{2\pi f_0}{c}, \quad k_x = \frac{n\pi}{l}, \quad k_y = \frac{m\pi}{m} \quad (17-14)$$

The transcendental equation (see Eq. 17-13) is solved to yield the resonant frequency of the radiating mode. A modified dielectric waveguide model has been proposed³⁹ to yield more accuracy in the calculation of the resonant frequency.

Cylindrical Ring Resonator In the case of a cylindrical ring⁴⁰ DRA of outer diameter $2a$, inner diameter $2b$, and height h , the resonant frequency of the $TM_{01\delta}$ can be given⁴¹ as

$$f_0 = \frac{c}{2\pi\sqrt{\epsilon_r}} \sqrt{\left(\frac{\pi}{2h}\right)^2 + \left(\frac{X_0}{a}\right)^2} \quad (17-15)$$

where X_o is represented as

$$\frac{J_1(X_0)}{Y_1(X_0)} = \frac{J_1\left(\frac{b}{a}X_0\right)}{Y_1\left(\frac{b}{a}X_0\right)} \quad (17-16)$$

where $J_1(x)$ and $Y_1(x)$ are the first-order Bessel functions of the first and second kind, respectively. By solving Eq. 17-16, one could have a plot of X_o as a function of b/a . The normalized Q -factor is obtained as a ninth order polynomial equation.

Numerical Methods

Numerical methods can be classified into frequency domain methods (such as spectral domain method, modal expansion, and method of moments) and time domain techniques (like FDTD, TLM, and FEM). Some of these techniques adopted for the analysis of DRAs that appeared in literature are shown next.

- MOM to investigate the effect of air gaps of cylindrical DRAs⁴²
- MOM to calculate internal field patterns of various modes of CRDA⁴³
- Model expansion used to compute mutual impedance between probe-fed hemispherical DRAs⁴⁴ and split CDRAs⁴⁵
- Use of mode matching techniques and Green's functions for hemispherical DRAs^{46,47}
- FDTD used to calculate circularly polarized patterns of cross-shaped DRAs⁴⁸
- FDTD methods to find input impedance of slot-fed RDRA⁴⁹
- TLM methods to compute input impedance of microstrip-fed multisegment DRAs⁵⁰
- FEM-based simulation techniques like HFSS
- Hybrid approach (modal expansion and spectral domain method) to analyze aperture-coupled DRA¹⁷

Green's Function Analysis of Hemispherical DRA The hemispherical DRA can be analyzed by using the Green's function of the spherical structures. Such analysis enables deriving Green's function for multilayer spherical DRA.

17.3 PROGRESS IN DRA RESEARCH

Various Geometries of DRAs

One of the attractive features of a DRA is that it can assume a number of shapes. Moreover the mode of operation and performance of a DRA can be varied by selecting a DR with desired structure. Hence a number of DRA geometries have been tried experimentally. The first systematic, theoretical, and experimental study was made on cylindrical¹² disk DRA geometry. Later geometries such as split cylinder,⁵¹ sectorized cylinder,⁵² cylindrical rings,⁵³ metallized DRAs,⁵⁴ triangular,⁵⁵ rectangular,¹³ notched rectangular DRA,⁵⁶ chamfered DRA,⁵⁷ conical,⁵⁸ elliptical,⁵⁹ spherical,¹⁴ hemispherical,⁶⁰ spherical cap,⁶¹ tetrahedral,⁶² perforated DRA,⁶³ stepped DRAs,^{64–66} and hybrid DRAs,^{67–71} have been reported. Some typical examples are illustrated in Figure 17-6. It was found that⁵³ DRAs operating at their fundamental modes radiate like an electric or magnetic dipole, which depends on the mode of excitation and geometry of the bulk dielectric material. Though several geometries have been introduced, the most studied and common structures are still the cylindrical and rectangular DRAs because of the simplicity in their design, fabrication, and analysis.

Wideband Techniques

The important and most common methods adopted for the fabrication of wideband DRAs can be broadly classified as single element methods, multiple DRAs, hybrid antennas, and DRA arrays. The single element method includes:

- Optimizing the feeding mechanisms and the DRA parameters
- Use of modified feed geometries (stub matching)
- Changing the shape of the DRA

FIGURE 17-6 Pictures of DRs with various shapes

- Introduction of air gap between the ground plane and DR
- Reducing the dielectric constant of DR
- Use of parasitic coupling with different resonators

There are reports^{72–74} regarding the bandwidth enhancement of rectangular, cylindrical, and elliptical DRAs employing microstrip matching stub. Though the bandwidth is enhanced, this technique worsens the cross-polarization level, which is undesirable in many applications.

The DRA geometries have been tailored to yield better performance. The different DRA geometries reported are described in the preceding subsection. A wide range of bandwidths has been reported based on the feeding techniques and DRA parameters. Modification of the DRA structure (see Figure 17-7) in the form of a stepped pyramid has been reported to have an ultra wideband as high as 60 percent.⁶⁶ The similar stepped stair structure has also been reported with cylindrical DRA.⁶⁷

Conical⁷⁵ and split conical⁷⁶ DRAs shown next (see Figure 17-8) are also reported as potential wideband candidates. A further enhanced bandwidth was observed with inverted conical DRAs. Split conical DRAs⁷⁷ offer still higher bandwidth (about 50 percent for DR of $\epsilon_r = 12$, $a = 22.5$ mm, $b = 49$ mm, and $h = 52$ mm), as shown in Figure 17-9. However, the split structures have the drawback of exciting higher-order modes, which perturbs uniform radiation within the middle of the band, as shown in Figure 17-10.

Another novel single-element DRA structure that attracted attention because of higher bandwidth is tetrahedral. An inverted (truncated) tetrahedral DRA⁷⁸ as shown in Figure 17-11 exhibits a wide bandwidth of about 40 percent with parameters as described in Figure 17-12. Compared with conical DRA, this structure has the advantage of a uniform radiation pattern (see Figure 17-13).

Yet another novel geometry (shaped DRA), which has attracted recent attention, is shown in Figure 17-14. The geometry is an inverted L-shaped cylindrical DRA, which is examined⁷⁹ for wireless applications covering four wireless bands as labeled in Figure 17-15. About 40 percent impedance bandwidth with 8 dBi peak gain is demonstrated.

Introduction of air gaps between the ground plane and DRA has proved⁸⁰ an efficient method to enhance the bandwidth. This normally results in an increase of resonant frequency and decrease in Q -factor. This method could attain an impedance bandwidth of up to 40 percent.⁸¹ Insertion of low-permittivity substrates in place of air gaps was also tried.⁸²

(a)

(b)

FIGURE 17-7 (a) Geometry; (b) Measured vs. computed reflection coefficients of stepped DRA

FIGURE 17-8 Conical and split conical DRA geometries for wide-band operation

Use of cylindrical rings⁸³ instead of cylindrical DRAs reduces the effective dielectric constant and hence increases the bandwidth. In this case also, introduction of an air gap between the DRA and the ground plane⁸⁴ can further improve bandwidth.

Significant improvements in bandwidth of rectangular DRAs have been reported by the use of notched structure⁸⁵ (see Figure 17-16). The idea is to effectively lower the dielectric constant and Q -factor to enhance bandwidth. Further tuning in dimensions can result in a dual band operation. With this technique a notched rectangular DRA with 32 percent bandwidth is reported, while the solid equivalent structure (rectangular DRA) resulted in only 10 percent bandwidth. In addition to the increased bandwidth, this geometry needs a hole drilled to insert the probe, which results in easier fabrication.

The second class of broadband DRA fabrication (multiple DRAs) methods consists of

- Loaded DRA with different dielectric materials
- Cavity backed DRAs
- Stacked DRAs
- Embedded DRAs
- Hybrid antennas (include DRA loaded with microstrip patch, DRA loaded monopole, etc.)

FIGURE 17-9 Split cone DRA (a) parameters and (b) its input impedance

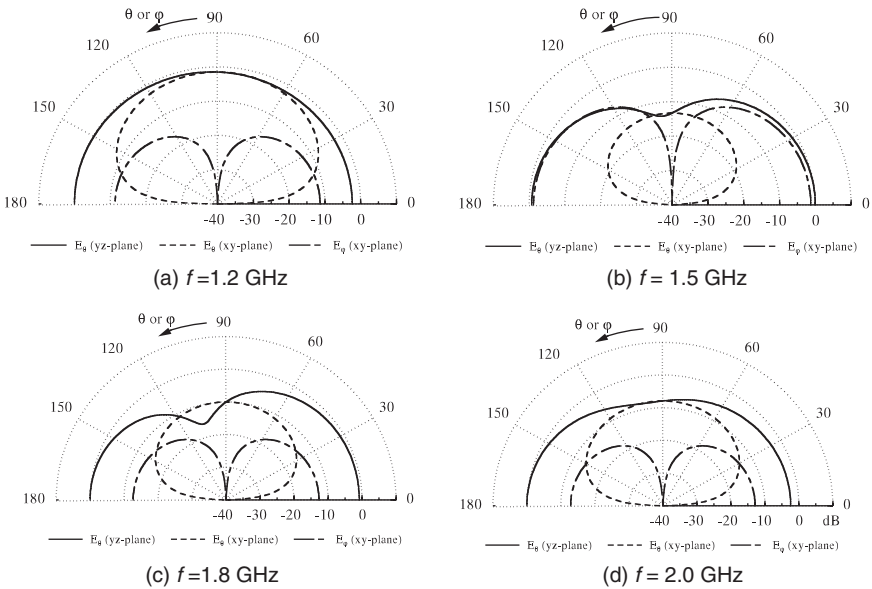

FIGURE 17-10 Radiation patterns of the antenna in Figure 17-9, with $b_1 = 4.9$ cm, $b_2 = 2.25$ cm, $h = 5.2$ cm, $w_L = 1.92$ cm, $h_w = 0.5$ cm, and $\epsilon_r = 12$ at different frequencies

Disk loaded DRAs⁸⁶ were reported mainly for frequency tuning and bandwidth improvement. The loaded disk can be either metallic or dielectric. However, in either case the disk perturbs the resonant frequency of the DRA; hence, disk size should be carefully selected.

Cylindrical DRAs backed by hemispherical cavity have been used⁸⁷ as a broadband antenna. The structure yielded 38 percent impedance bandwidth. The only drawback of this antenna is the bulky structure.

FIGURE 17-11 Geometry of truncated tetrahedral DRA

FIGURE 17-12 Computed and measured reflection coefficients of a truncated tetrahedron with $L_U = 6.4$ cm, $L_L = 2.5$ cm, $h = 2.6$ cm, $w_x = 0.55$ cm, $w_L = 1.15$ cm, and $\epsilon_r = 12$

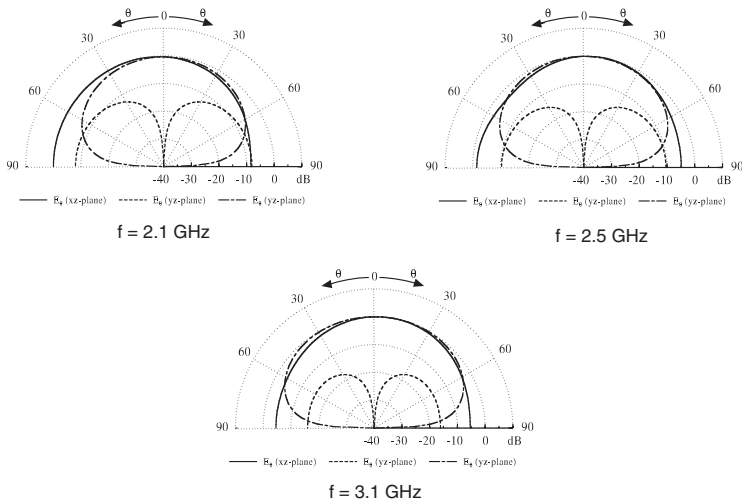

FIGURE 17-13 Computed radiation patterns of a truncated tetrahedron at different frequencies with $L_U = 6.4$ cm, $L_L = 2.5$ cm, $h = 2.6$ cm, $w_x = 0.55$ cm, $w_L = 1.27$ cm, and $\epsilon_r = 12$

Stacking of DRAs^{88–90} was reported as an efficient technique to improve the gain, bandwidth, and radiation performances. Further increase in bandwidth can be achieved by the introduction of air gaps. Another advantage is that a single probe can be used for the excitation of all DRs. Bandwidth in the range of 25–35 percent has been reported with this geometry.

Embedding of one DRA in another is a new method for bandwidth enhancement. This can be done either with both the DRs having the same permittivity,⁹¹ or with the inner and outer DRs having different permittivity.⁹² The latter has reported an impedance bandwidth of over 50 percent, when $a_2 = 4$ mm, $h_2 = 2$ mm, and $\epsilon_r = 12.3$ and $a_1 = 5.5$ mm,

FIGURE 17-14 Shaped DRA: DCS-WLAN bands

FIGURE 17-15 Return loss characteristics of shaped DRA with possible bands of operation

FIGURE 17-16 Geometry and measured return loss of notched DRAs

$h_1 = 6$ mm, and $\epsilon_{r1} = 4.1$. The antenna is placed on top of a narrow slot with length 5.5 mm and width 0.5 mm. The slot is excited parasitically with a $50\ \Omega$ microstrip line on a substrate of thickness 0.813 mm, dielectric constant 3.38, and extended stub of 4 mm.

It has also been observed that the geometry with higher dielectric constant material touching the slot provides better matching.

Mainly two types of DRA-based hybrid antenna structures are reported: DRA-loaded microstrip patch antennas and DRA-loaded monopole antennas.

Microstrip patch antennas possess many advantages like light weight, compactness, high gain, low profile, easy fabrication, etc. However, they suffer from conduction losses and low-impedance bandwidth. There are reports that the bandwidth performance of a microstrip antenna can be improved by loading with a DRA.^{71,93} Bandwidth of about 24 percent has been achieved with this technique. Patch antennas loaded with stacked DRAs⁹⁴ were also reported to yield better bandwidth.

FIGURE 17-17 Embedded DRA

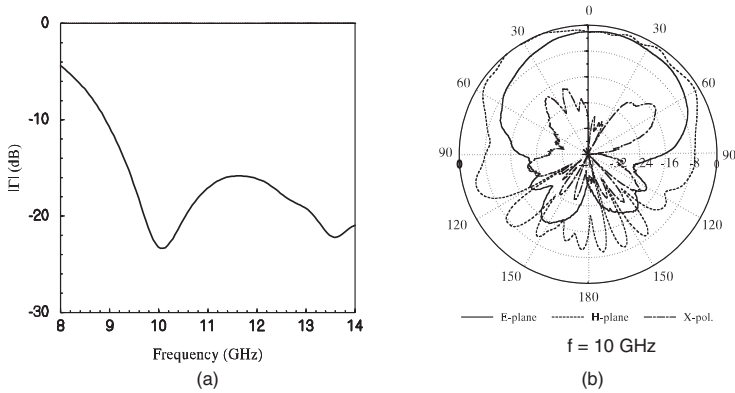

FIGURE 17-18 (a) Measured reflection coefficients and (b) radiation patterns of embedded DRA excited by narrow slot

One of the recent techniques developed to have an ultra wideband hybrid antenna⁶⁹ is shown in Figure 17-19. Here a dielectric ring resonator surrounds a monopole antenna. Both are centered at the same axis and the monopole acts as a quarter-wavelength radiator as well as a feed for DRA. The DRA is designed to excite in the dominant $TM_{01\delta}$ mode, which has a circular symmetric field distribution similar to that of a monopole. A further in-depth investigation on the design parameters of this structure was also reported.⁹⁵ For wideband operation the monopole is designed to operate at the lower end of the frequency spectrum, while DRA operates toward the upper end. The design parameters can be selected to have separate frequencies, so that dual band operation occurs.

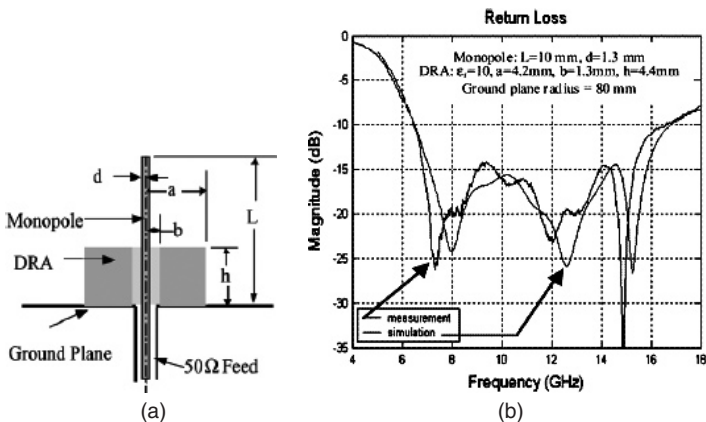

FIGURE 17-19 (a) Cross sectional view of monopole-fed DRA and (b) wideband characteristics

More recently, a compact coplanar waveguide-fed planar monopole-DRA structure has been reported⁹⁶ with about 50 percent bandwidth when a DR of permittivity 38 was used (see Figure 17-20).

17.4 DRA ARRAYS

DRA elements of proper geometry can be assembled and fed in a suitable way to modify their gain, bandwidth and radiation performances and hence can be advantageous over a single element. These DRA arrays⁹⁷⁻¹⁰² find applications in terrestrial applications as well as radars. The performance of an array depends on the geometry and dimensions of individual elements, number of elements, their spacing, mode of operation and feeding techniques adopted. The developed DRA arrays can be broadly classified as linear DRA arrays and planar arrays.

FIGURE 17-20 Geometry of hybrid CPW-fed planar monopole/dielectric resonator antenna. $L_G = 25$ mm, $W_G = 10$ mm, $L_M = 18$ mm, $\epsilon_r = 4.4$, $h = 1.6$ mm, $L_S = 50$ mm, $W_S = 30$ mm, $S = 3$ mm, $G = 0.3$ mm, $\epsilon_{dr} = 38$, $h_{dr} = 3.83$ mm, $D_{dr} = 16.4$ mm

Linear DRA Arrays

A linear DRA array produces radiation patterns with narrow beamwidth in a plane parallel to the array axis and a broad beamwidth in the orthogonal plane. The phase and amplitude of excited radiation in the element can be controlled to have a specific beam shape. The most common excitation technique employed in this case is microstrip line methods. Linear DRA array excitation can be of (1) microstrip parallel feed, (2) microstrip series feed, (3) microstrip branch line feed, and (4) dielectric image guide feed. Figure 17-21 shows¹⁰³ the radiation patterns of a uniformly excited 32-element linear array of dielectric resonator disks. The elements are separated by a half wavelength, excited by coaxial probes, and arranged in the E -plane of the array. The radiation patterns are shown both without mutual coupling effects and with the mutual coupling effect. The radiation patterns are scanned at 0° , 30° , and 60° . It can be seen that

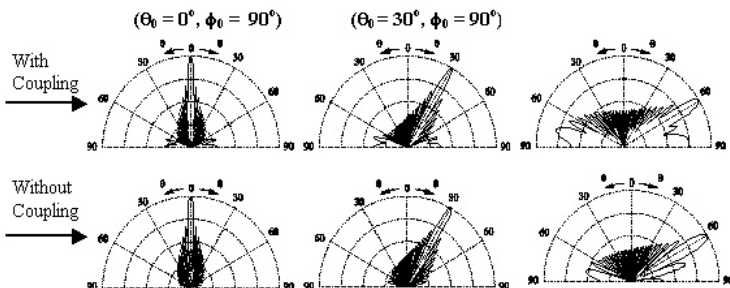

FIGURE 17-21 E -plane radiation patterns of 32 DRA elements with and without mutual coupling effect

FIGURE 17-22 Linear arrays of DRAs excited with corporate feed network

the desired scanning direction is achieved. The mutual coupling shows its effect with the low elevation angles from 60° to 90° .

Microstrip Parallel Feedline

This type of feed results in a more compact and smaller antenna network loss. Adjusting the spacing between the DRA and the stripline can control the coupling between them. Consider a linear array¹⁰⁴ as shown in Figure 17-22.

In this case four rectangular DRAs are fed via a slot aperture using a microstrip parallel network. The antenna system operates at 40 GHz. The measured gain is 6.2 dBi. The main disadvantage of this kind of feeding is the conductor and surface wave losses from the microstrip line.

Microstrip Series Feedline The use of series feeding results in a more compact and lower-loss antenna system compared with parallel feeds. However, series feeding suffers from reduced bandwidth due to increased phase errors from the designed frequency, since electrical path lengths are a function of frequency. In this case, two approaches can be applied for designing: the resonant approach¹⁰⁵ and the leaky-wave approach.¹⁰⁶ In the resonant approach (see Figure 17-23), the microstrip line terminates to an open circuit, which creates standing waves on the line.

In this case, when the number of elements is small, the amount of coupling from the microstrip line to each DRA element is low and this method better predicts radiation patterns. On the other hand, if the number of elements is high, very little energy will be left

FIGURE 17-23 Linear array of DRAs with series fed microstrip lines

FIGURE 17-24 Linear DRA array fed by branched microstrip lines

over to reach the open termination point to create the standing waves. In such cases, the radiation patterns can be more accurately predicted using leaky wave analysis.

The main drawback of series and parallel fed microstrip arrays is the need for more elements for better radiation performance, making the antenna system bulky.

Microstrip Branch Line Feed Branched microstrip line feed has been proposed as an alternative for series and parallel fed antenna arrays, which results in better coupling of energy between the elements and transmission line. An example of this type of DRA array¹⁰⁷ is depicted in Figure 17-24. Furthermore, this method enables a much more precise amplitude control than previous methods.

Dielectric Image Guide Feed The use of a low-loss dielectric image guide as a transmission line can reduce the losses due to conductor and surface waves that are generated in microstrip lines. This method could produce a significant radiation performance (especially in gain and efficiency) of a DRA array. A linear DRA array fed by a dielectric image guide¹⁰⁸ is shown in Figure 17-25.

However, it was observed that this kind of feeding could still result in lesser gain compared with a microstrip line unless transition was carefully designed. This is because

FIGURE 17-25 Dielectric image guide fed DRA array

FIGURE 17-26 Geometry of 8×8 planar DRA array

the spurious radiation from the feed transition into the dielectric image guide could degrade the benefits of low-loss dielectric.

Planar DRA Arrays

An example of an 8×8 array of DRA is provided to show the effect of the mutual coupling. The array geometry is shown in Figure 17-26. The radiation patterns for the array are shown in Figure 17-27. Again the effect of the mutual coupling is noticed only in the radiation patterns at the low elevation angle below 60° .

Figure 17-28 shows the geometry and the radiation patterns of a 4×4 stacked DRA array. Narrow slots excite the array. The radiation patterns show a front-to-back ratio of 16 dB.

One of the practical problems of the DRA array is assembling the individual elements and aligning them. Perforation techniques can be used to fabricate an array of DRAs from a single dielectric sheet, as shown in Figure 17-29. This also eliminates the difficulty of placing and bonding individual elements. Investigations on grid element DRA¹⁰⁹ arrays have shown that this array has better gain and bandwidth performance compared with microstrip fed arrays.

FIGURE 17-27 Radiation patterns of 8×8 uniformly excited planar DRA array

FIGURE 17-28 Geometry and radiation patterns of 4×4 planar stacked DRA array

Sequential Rotation Arrays Sequential rotation arrays¹¹⁰ are mainly intended to improve the axial ratio performance of the DRA elements. Figure 17-30 shows some typical examples of these arrays. The main challenge in the design and fabrication of this type of array is to allocate the feed network that can provide the required amplitude and phase to each radiating element.

Reflect Array DRAs DRA is used as a reflect array operating at 30 GHz. A 529-element reflect array DRA¹¹¹ was machined from a single sheet of dielectric substrate. Later the surface was fused with rigid metallic flat plate. The measured radiation patterns showed again over 24 dB at 30 GHz and sidelobe level below 18 dB.

18.1 BASIC LENS OPERATION

Lenses and reflectors (see Chapter 15) are used as collimating elements in microwave antennas. Reflectors have a single degree of freedom (the reflector surface), have no internal loss, have low reflection loss, have no chromatic aberration, are relatively easy to support, and can be perforated to reduce weight and wind loads. Lenses have up to four degrees of freedom [inner surface, outer surface, index of refraction n , and (for constrained lenses) inner- versus outer-surface radiator positions], have no aperture blockage by the feed, have internal and surface-reflection losses, must be edge-supported, and are relatively heavy and bulky. In general, if a reflector can provide the required performance for a given application, it should be used. However, since lenses are more versatile, especially in wide-scan-angle performance, they are used in many applications that do not require greater flexibility of a phased array.

The methods for determining radiation-pattern characteristics from an aperture (amplitude and phase) distribution, including deviations from desired distributions, are derived and discussed in Chapter 3. Lens applications are discussed in several other chapters and are only suggested in this chapter. The literature¹⁻⁶ contains summaries of most lens types and list a number of references. The material in Jasik¹ is the basis of this chapter, and many sections are only updated; however, the section on artificial dielectric materials is not repeated here.

Some microwave lenses are adapted directly from optics, but microwave antennas generally use only a single element since multielement designs common in optics are generally too bulky and heavy for microwave applications. However, several techniques are available at microwave frequencies that permit specialized designs which are difficult, if not impossible, to use at optical frequencies; these techniques include nonspherical lens surfaces, artificial dielectric materials, constrained and geodesic media, and variable n with position in the media.

Lenses are designed to collimate one wavefront into another by using ray tracing on the basis of the law of the optical path that all rays between wavefronts (or phase fronts) have equal optical path lengths and on the application of the Fresnel equations (Snell's law plus polarization effects) at the lens surfaces. The lenses discussed in this chapter collimate a spherical or cylindrical wavefront produced by a point or line-source feed into a planar or linear wavefront; i.e., they are focused at infinity. In practice, however, complex feeds can be used since performance does not deteriorate rapidly with small off-axis feed displacement. Other lens designs have limited application at microwave frequencies.

Figure 18-1 shows two ways of achieving lens designs; in methods *a* and *b* rotational lenses are used in conjunction with a point-source feed (the term *rotational* means that the surfaces of the lens are obtained by revolution of a curved line about the lens axis), while in methods *c* and *d* cylindrical lenses (i.e., lenses whose surfaces are generated by moving a curved line perpendicularly to itself) are used in conjunction with a line-source feed.

At microwave frequencies, natural homogeneous dielectric media always have $n > 1$ (i.e., a phase velocity less than that of light in free space), which leads to the convex lens shapes of Figure 18-1*a* and *c*. However, artificial or fabricated media may be constructed with a range of n from $n \gg 1$ to $n \ll 1$. Examples of lenses constructed with $n < 1$ are shown in Figure 18-1*b* and *d*, where it is seen that a concave shape is required to focus a beam. In general, the types having $n < 1$ are highly dispersive (i.e., n varies rapidly with frequency), while those having $n > 1$ are nondispersive. Thus lenses having $n < 1$ are usually limited to small frequency bandwidths, while lenses having $n > 1$ may be designed to operate over an octave or more.

FIGURE 18-1 Basic lens configurations

18.2 LENS-SURFACE FORMULAS FOR $n > 1$

Common shapes for $n > 1$ media lenses are shown in Figure 18-2; all are single-degree-of-freedom, single-focal-point lenses because either they refract at only one surface, or one surface is fixed during the design. The formulas given in the figure apply to both rotational and cylindrical surfaces.

Single Refracting Surface, $n > 1$

The lenses in Figure 18-2a–d refract at only one surface. In lenses a–c, refraction occurs at the inner surface (adjacent to the focal point) and in lens d, at the outer surface. In each case, the nonrefracting lens surface is parallel to a wavefront. The lens-surface formulas in Figure 18-2 are derived by equating the optical-path length of a general ray to that of the central ray from an on-axis point at a distance f from the inner surface to a planar wavefront perpendicular to the axis; for example, for the lens in Figure 18-2a, the relation is $r = f + n(r \cos \theta - f)$, which can be easily manipulated into the form given in Figure 18-2a, a hyperbola. The feed is located at the focal point farthest removed from the inner surface.

A disadvantage of this type of lens is that reflections from the nonrefracting surface will converge at the focal point, since the surface is coincident with a wavefront, and cause a feed-line mismatch approximately equal to the surface-reflection coefficient. It is desirable that this surface reflection be either prevented from entering the feed line or eliminated. A high feed-line voltage-standing-wave-ratio (VSWR) may be avoided by using a ferrite

 FIGURE 18-2 Lens-shape designs for $n > 1$ media

isolator, by tilting the lens slightly (as in Figure 18-3a) so that the reflected energy will be refocused off the feed, or by displacing half of the lens a quarter wavelength (in the lens medium) along the axis with respect to the other half (as in Figure 18-3b) so that reflections from the two lens halves are 180° out of phase and create a null at the feed center. These methods have been found to be effective in reducing the feed-line VSWR; however, they

FIGURE 18-3 Reduction of feed VSWR by (a) lens tilt and (b) quarter-wavelength displacement of half of the lens

do not eliminate the other effects of surface reflection, such as loss of gain and increase in sidelobe level. Whenever these factors are important, the surface-matching techniques to be described later are recommended. Avoiding feed-line mismatch by the technique of Figure 18-3a depends on low wavefront distortion for small off-axis feed displacements. Analysis⁷ of aberrations due to feed displacement from the focal point shows that coma is the predominant term that limits performance, that coma is reduced as focal length and n are increased, and that the coma for a large- n hyperbolic lens is twice that for an equivalent-focal-length paraboloidal reflector. Although this is not usually necessary for small lenses, if the technique of Figure 18-3b is used for large-diameter lenses, the two lens halves should be designed with different focal lengths.

These lenses may be constructed with natural dielectric materials and artificial delay media. Kock⁸ developed a number of artificial delay media and constructed lenses of the type shown in Figure 18-2a and b with these media.

Two Refracting Surfaces, $n > 1$

Microwave lenses that refract at both surfaces have not been used as frequently as the single-refracting-surface types because their performance is not sufficiently better to justify the more difficult design problems.

Lens designs that meet the Abbe sine condition (to eliminate coma for small off-axis feed displacements) have been developed.⁹ The planoconvex single-focal-point lenses in Figure 18-2e and f almost satisfy the Abbe sine condition for $n = 1.6$ and an $f/D = 1$. An experimental 50-wavelength-aperture lens had good performance over a total scan angle of 20° .

A lens with two refracting surfaces has two degrees of freedom that should permit designs with two focal points. Several investigators¹⁰⁻¹² have developed bifocal design techniques that are iterative and do not lead to closed-form solutions. These lens designs are two-dimensional (cylindrical) and symmetrical about the lens axis. One technique¹⁰ assumes prisms at the lens edges and represents surfaces with even-order polynomials to permit iterative ray tracing. Another technique¹¹ involves a lattice method wherein points on the two lens surfaces are determined by alternating between the two focal points for ray tracing. Brown¹² uses prisms at the lens edges and the lattice method for determining the surfaces. For $n = 1.6$ and focal points at $\pm 20^\circ$, the resulting lens is almost planoconvex (the almost linear surface is slightly concave), very nearly that obtained in Sternberg.¹⁰ Zoning is achieved by designing separate lenses for each of the zones. Three-dimensional lenses were obtained by rotating the two-dimensional designs about the lens axis. In these

lenses, astigmatism is large and limits the beam-scan angles to about 20° . Brown¹² shows experimental data for 50-wavelength-diameter lenses with $n = 1.6$ and focal points at $\pm 20^\circ$ for f/D 's from 1 to 2.

Zoning Formulas, $n > 1$

In the case of physically large lenses, the use of continuous surfaces (as in Figure 18-2a, *d*, and *e*) results in a massive structure that is difficult to produce without imperfections, and the long path lengths in the medium make its index of refraction highly critical. To alleviate these disadvantages, use is commonly made of discontinuous, or zoned, surfaces as in Figure 18-2b, *c*, and *f*. Ray paths through any two adjacent zones are designed to differ from each other by exactly 360° (or a whole multiple thereof) at the design frequency so that a plane wavefront results on the outer side of the lens.

Figure 18-2b and *c* gives the surface-shape formulas for zoned versions of the lens of Figure 18-2a, while Figure 18-2f shows the zoned counterpart of Figure 18-2e; the use of integers $K = 1, 2, \dots$ gives a family of lenses that has a focal point at $x = -f$ and produces plane wavefronts that differ from each other in phase by integral multiples of 360° . In the use of these formulas, a thickness d on the axis is chosen and the central zone of the surface is computed for $K = 1$. At the radius for which the lens thickness is equal to the minimum allowed by mechanical considerations, the second zone is computed for $K = 2$. In a similar manner, additional zones are computed with $K = 3$, etc., until the desired lens diameter is attained. If the minimum allowable thickness is d_{\min} , the maximum thickness is approximately $d_{\min} + \lambda/(n - 1)$, where λ is the design wavelength.

Effects of Zoning on Aperture Illumination, $n > 1$

The aperture illumination of a lens is determined by a number of factors, one of which is the lens-material loss that is proportional to lens thickness. In an unzoned lens with $n > 1$, this loss is larger for on-axis rays where the lens has maximum thickness than for edge rays. This leads to a more nearly uniform amplitude distribution than would be estimated without considering loss. Since a zoned lens is thinner and therefore has less loss, the aperture illumination is less strongly affected.

Certain defects in the aperture illumination usually occur with zoned lenses and should be considered carefully in the lens design. For example, Figure 18-4a shows how shadowed bands (without energy) occur in the aperture field of a refracting outer surface. Inspection of the figure reveals that there is no way in which the zonal boundary can be shaped to eliminate the shadow. These nonilluminated bands produce aperture illumination discontinuities that increase sidelobe levels and decrease gain.

A second type of defect occurs when a first refracting surface is zoned, as in Figure 18-4b. In this case, the rays between rays *a* and *b* are not properly refracted by the lens and are scattered in undesired directions. Although there is no shadowing in this case, the aperture illumination is perturbed at the zone boundaries and deteriorates the expected radiation pattern.

However, zoning without shadowing or energy loss is possible if it is done on a nonrefracting surface of the lens. Figure 18-4c shows an example for the case of a plane outer surface. The surface of the step between zones must be perpendicular to the zoned surface. This type of zoning should provide the most satisfactory aperture illumination, but disturbance still exists along the zone boundaries because of phase differences between the rays just inside and outside the dielectric surface. In the special instance of a cylindrical lens in which the **E** vector is everywhere perpendicular to the step surface, this disturbance may be avoided by covering the zone boundaries with thin conducting sheets.

FIGURE 18-4 Effects of zoning on aperture illumination, $n > 1$

Bandwidth of Zoned Lenses, $n > 1$

The surface-shape design of an unzoned constant- n lens is independent of frequency. However, as may be seen from the formulas in Figure 18-2, zoning introduces a frequency dependence so that a zoned lens has a limited bandwidth of satisfactory operation. Rays through adjacent zones will differ by exactly 360° only at the design frequency. If the lens has a total of N wavelength steps between the central and edge zones, the effective path-length difference between a ray through the edge zone and a ray through the central zone is $N\lambda_0$ at the design wavelength λ_0 and $N\lambda$ at any other wavelength λ , where N is 1 less than the K of the outermost zone. The phase difference, in wavelengths, of the edge zone compared with the central zone is $-Nd\lambda$, where $d\lambda = \lambda - \lambda_0$. Since the total bandwidth is approximately $100(2d\lambda/\lambda)$ percent, if a phase difference of $\pm\lambda/8$ is allowed, the bandwidth of a lens having N wavelength steps is $25/N$ percent. Thus a zoned lens has an approximate bandwidth of 5 percent for $N = 5$ if only zoning effects are present. However, since there are other sources of phase error and it is necessary to allocate the total allowable phase error among all error sources, the bandwidth may be smaller than indicated earlier.

18.3 FACTORS AFFECTING GAIN AND SIDELobe LEVELS OF LENS ANTENNAS

The gain of a lens antenna is reduced by a number of factors that include the amount of feed energy not incident upon the lens (spillover loss), the effects of lens shape on aperture illumination, dissipation loss in the lens medium, and reflection from the surfaces.

Spillover Loss

Spillover may be avoided if the feed horn is extended to the lens edges; however, this is usually not done, since lens-surface reflections are reflected by the horn walls and radiated from the lens in undesired directions, thereby increasing sidelobe levels. The horn walls can be covered with absorbing material to reduce the energy in the reflected waves, but with this technique the antenna gain is reduced since feed energy is also absorbed.

In applications in which low sidelobe levels are important, the use of a multielement (array) feed to tailor the aperture illumination and reduce spillover is recommended. Also, surface matching is recommended to permit the use of an extended horn, increase gain, and reduce sidelobe levels.

Effect of Lens Shape on Aperture Illumination

The aperture amplitude distribution is a function of the feed radiation pattern, the shape of the lens, lens-surface reflections, and lens losses. Jasik¹ and Silver² derive the relations for conversion from the power per solid angle radiated by the feed to the power per unit area in the aperture for several lens types and plot the conversion factors for several sets of lens parameters. In general, for $n > 1$ lenses, the conversion factor is < 1 ; for $n < 1$ lenses, the factor is > 1 ; therefore, if a given feed is used for the two lens types, the $n < 1$ lens will have a higher edge illumination than the $n > 1$ lens.

Dissipation Loss in Lens Media

The dissipative attenuation constant for a dielectric medium is approximately $27.3 (\tan \delta) n$ (dB/wavelength), where n is the index of refraction and $\tan \delta$ is the loss tangent of the medium. Since the maximum thickness of a zoned $n > 1$ lens is approximately $\lambda/(n - 1)$, the upper limit for lens attenuation is approximately $27.3 (\tan \delta)n/(n - 1)$ (dB). Therefore, for most practical materials the maximum dissipation loss is several tenths of a decibel. Von Hippel¹³ contains extensive dielectric-constant and loss-tangent data for many dielectric materials over a large range of frequencies and temperatures.

Reflections from Lens Surfaces

The air-to-dielectric interface at each lens surface produces reflected and transmitted waves. The amplitude and phase of waves are obtained by the application of Fresnel's equations and depend on n , the angle of incidence, and the polarization relative to the incidence plane (a plane through the incident ray and the surface normal). Since there are reflections at both lens surfaces, the effects of internal multiple reflections are determined by the ray path lengths between the surfaces. The thickness of a typical lens varies appreciably over its aperture so that, with the transmitted waves adding in various phases, there are a number of almost sinusoidal variations in amplitude and phase over the aperture. For most lenses, incidence angles are less than 45° so that reflection losses can be averaged over all incident polarizations and angles to obtain an approximate lens reflection loss of $8.69(n - 1)^2/(n + 1)^2$ dB. For an $n = 1.6$ lens, this reflection loss is less than 0.5 dB. However, sidelobe levels are seriously increased and for most lenses are limited to values of about -20 dB.

These effects may be reduced by matching the lens surfaces.¹⁴⁻¹⁶ For near-normal incidence angles, this can be accomplished by adding to each surface a quarter-wavelength-thick coating (in the material) with an index of refraction of $(n)^{1/2}$, where n is the lens-material index of refraction. If it is necessary to match for nonnormal incidence angles, the coating thickness and index of refraction may be modified as discussed in Jasik.¹

For many lens materials, a coating material with the correct index may not be available; in that case, surface matching may be performed by machining the lens surfaces to the configurations shown in Figure 18-5 and discussed in detail in the literature.^{1,14-16} The improvement that can be obtained in lens performance by lens-surface

FIGURE 18-5 Simulated quarter-wavelength matching transformers for lens surface

FIGURE 18-6 Radiation patterns of unmatched and matched lenses

matching¹⁶ is shown in Figure 18-6; however, these lenses were matched with artificial dielectrics not discussed in this chapter.

18.4 LENS-SURFACE FORMULAS FOR $n > 1$

The lens formulas given in Figure 18-2 apply for $n < 1$ as well as for $n > 1$; however, for convenience, the lens-surface formulas for $n < 1$ media planoconcave lenses are shown in Figure 18-7 and apply to both rotational and cylindrical surfaces. These are single-refracting-surface, single-focal-point lenses since the planar outer surface is fixed during the design to lie on a wavefront. The inner surface is an ellipse with foci on the axis; the feed is located at the focus farthest removed from the inner surface. Reflections from the outer surface converge at the focal point as for $n > 1$ lenses and can be eliminated by techniques used for those lenses.

For the stepped inner surface in Figure 18-7b, shadow bands at the steps cannot be avoided, as may be seen in Figure 18-8. Although all the rays emanating from the feed are collimated by the lens, the steps cause discontinuities in the aperture illumination. As in the case of $n > 1$ lenses, zoning can be accomplished without shadowing or energy loss only if the steps are formed in the equiphase outer surface, but the resulting meniscus-type lens shape is more difficult to manufacture and to support than the flat shape of Figure 18-7b.

FIGURE 18-7a and b Lens-shape for $n < 1$ media

FIGURE 18-8 Shadows introduced by zoned lens in Figure 18-7b

The maximum thickness of the stepped lens for $n < 1$ is equal to $d_{\min} + \lambda/(1 - n)$, where d_{\min} is the minimum thickness permitted in the mechanical design. The bandwidth limitation due to zoning alone is the same as for $n > 1$ lenses. However, the bandwidth of the actual lens is considerably less than this when the frequency sensitivity of n is taken into account, since all known media having $n < 1$ exhibit a large rate of change of n with frequency. Thus, in the common case of a metal-plate zoned lens having the shape shown in Figure 18-7b, if $\pm\lambda/8$ phase error is allowed, the bandwidth is approximately $25n_0/(1 + (N + 1)/n_0)$ percent, where n_0 is the n at the design frequency and N is the number of one-wavelength steps between the central and edge zones. In the case of frequency-sensitive media, zoning increases the bandwidth of a lens over that of an equivalent unzoned lens by a factor of 2 or 3 because the ray path lengths in the dispersive medium are greatly reduced by zoning. The bandwidth of a given lens antenna may be extended considerably if the antenna application permits moving the feed position along the lens axis as a function of frequency, since defocus is the principal effect of a frequency change.

The lenses in Figure 18-7 may be constructed with artificial dielectric, metal-plate, or waveguide media. An excellent summary of artificial dielectric media is contained in Jasik.¹ Metal-plate and waveguide media are discussed in the next section. Kock¹⁷ used a number of techniques to construct metal-plate lenses with both circular and rectangular apertures. Figure 18-9 is a photograph from Kock⁸ of a stepped 96-wavelength-aperture, $F/D = 0.96$, metal-plate lens that has a useful bandwidth of about 5 percent. Most early metal-plate lenses used the designs and techniques of Kock. Additional $n < 1$ lenses are discussed in Section 18.6.

FIGURE 18-9 An $F/D = 0.95$ zoned lens

18.5 METAL-PLATE AND WAVEGUIDE MEDIA

Rays incident on natural dielectric and many artificial dielectric media obey Snell's law at the surface. A metal-plate medium (composed of parallel, equally spaced plane metal sheets) constrains rays in the medium to paths parallel to the plates; therefore, Snell's law is not obeyed for incident rays in a plane normal to the plates (see Figure 18-10), while it is obeyed for rays incident in a plane parallel to the plates (see Figure 18-11a). A waveguide medium constrains rays in the medium to paths parallel to the waveguide axis (see Figure 18-11b); therefore, Snell's law is not obeyed for any incidence angle.

FIGURE 18-10 Constrained refraction in the H plane

Both metal-plate and waveguide media operate in the fundamental TE mode of propagation, and since the phase velocity exceeds the velocity of light in free space, $n < 1$. If the cutoff wavelength is λ_c , then $n = [1 - (\lambda/\lambda_c)^2]^{1/2}$ for an operating wavelength λ . For both parallel plates spaced a apart and a waveguide of width a , $\lambda_c = 2a$. For a regular hexagon of width a between parallel sides, $\lambda_c = 1.792a$. For a circular waveguide of diameter a , $\lambda_c = 1.705a$.

When parallel plates are used, an E -field component perpendicular to the plates must be avoided, since this excites a TEM mode that propagates between the plates with the velocity of light ($n = 1$) and the energy would not be focused. For square, circular, and

FIGURE 18-11 Unconstrained (a) and constrained (b) refraction in the E plane

hexagonal cross-section waveguide media, n is independent of incident polarization, and these structures can be used for any polarization. A rectangular cross-section waveguide medium has different values of n for the two principal linear polarizations.

Limitations on Metal-Plate Spacing and Rectangular-Waveguide Width

A basic limitation on the choice of plate spacing a results from the fact that the medium must operate between the cutoff frequencies of the fundamental and the next higher TE modes. For air-filled structures, this requires that $0.5 < a/\lambda < 1.0$; this range of a/λ corresponds to a range in n of $0 < n < 0.866$. However, a further restriction on the plate spacing must be imposed if the existence of diffracted waves due to the grating effect is to be avoided. It will be shown later how such diffracted waves cause considerable loss of transmitted power, distortion of the aperture illumination function, and consequent loss of gain and increased sidelobe levels. The presence of one diffracted wave is shown in Figure 18-10. This occurs in the direction in which the diffracted waves from the individual plate edges combine in phase. It can only occur when the plate spacing exceeds a particular value and will be avoided if the following condition is met:

$$[\lambda \sin \alpha / (a + t)] - 1 > |\sin \theta_1| \quad (18-1)$$

where t is the wall thickness and the other symbols are defined in Figure 18-10. This is also the condition for avoiding a diffracted wave when the incident wave is in the medium and the transmitted ray emerges at angle θ_1 . For $\alpha = 90^\circ$, this is the familiar expression for avoiding grating lobes from a phased array: $s = a + t < \lambda / (1 + \sin \theta_1)$. The limiting values of Eq. 18-1 are shown graphically in Figure 18-12, where the angle θ_1 of the ray in free space is plotted versus $(a + t)/\lambda$ for different values of α from 30 to 90° . For each particular value of α , the region to the lower left of the curve gives the ranges of θ_1 and $(a + t)/\lambda$ in which diffracted waves are avoided.

Reflection and Transmission at an Interface

For the case of the E field parallel to the plane of incidence and parallel to the plates (see Figure 18-11a), the power-reflection coefficient is

$$r^2 = \sin^2 (\theta_1 - \theta_2) / \sin^2 (\theta_1 + \theta_2) \quad (18-2)$$

where θ_1 is the ray angle in free space and θ_2 the ray angle in the parallel-plate medium, both angles being measured from the normal to the surface. The plates are assumed to be very thin; however, thick plates are treated in Primich¹⁸ for $\theta_1 = 0$ and $\alpha = 90^\circ$. Equation 18-2 also holds true for a wave incident from the metal-plate region. The reflected ray is then within the metal-plate region at an angle $-\theta_2$. Note that Eq. 18-2 also applies for a solid dielectric with E perpendicular to the plane of incidence. Equation 18-2 and Snell's law of refraction hold for all angles of incidence [if $0.5 < (a + t)/\lambda < 1.0$], and diffracted waves do not occur. However, this is not true of parallel polarization incident on a constrained medium (see Figure 18-11b), and a solution for that case is unavailable.

Considerable published information is available for the case of E perpendicular to the plane of incidence and parallel to the edges of a set of very thin plates (see Figure 18-10). The basic analysis is due to Carlson and Heins,¹⁹ while further theoretical work was done

FIGURE 18-12 Limiting angle of incidence for pure specular reflection versus plate spacing

by Lengyel,²⁰ Berz,²¹ and Whitehead.²² In the range of θ_1 free of diffracted waves, as given by Eq. 18-1 and Figure 18-12, the power-reflection coefficient for a wave incident on an array of plates is

$$|r|^2 = \left[\frac{\cos(\theta_1 + \psi) - n}{\cos(\theta_1 + \psi) + n} \right] \left[\frac{\cos(\theta_1 - \psi) - n}{\cos(\theta_1 - \psi) + n} \right] \quad (18-3)$$

where $\psi = 90^\circ - \alpha$ is the angle between the normal to the boundary and the plates. The specularly reflected wave propagates at angle $-\theta_2$. Because of reciprocity, this formula also applies to waves in the plate region incident upon the free-space boundary, where the waves between the plates are phased to produce a transmitted wave propagating at angle θ_1 from the normal. For normal incidence and $\alpha = 90^\circ$, Eq. 18-3 reduces to $r^2 = (1 - n)^2 / (1 + n)^2$, which also applies to a solid-dielectric boundary. In the range of θ_1 where diffracted waves may exist, Eq. 18-3 is no longer valid. Formulas for this range have been derived by Lengyel,²⁰ Berz,²¹ and Whitehead²² and are much more complicated than Eq. 18-3.

Figure 18-13 shows the percentage of incident power transmitted into a metal-plate medium for the conditions of Figure 18-10 and $\alpha = 90^\circ$. To the left of the break in each curve (points D), the nontransmitted power is reflected in the specular reflected wave, while to the right of the break the nontransmitted power is divided between the specular reflected wave and a diffracted wave. The power loss in the latter region is large and should be avoided in lens design. At points S, the angle θ_d of the diffracted wave is equal to θ_1 of the incident wave (see Figure 18-10). When $\alpha = 90^\circ$, the reflection and transmission quantities are not symmetrical about $\theta_1 = 0$.

FIGURE 18-13 Percentage of power transmitted into metal-plate medium, $\psi = 0$

The discontinuity effect at the boundary of the metal-plate medium also results in a phase change. Formulas giving this change have been derived by Lengyel,²⁰ Berz,²¹ and Whitehead.²² Graphical plots of this phase change versus the angle of incidence are given by Berz and Whitehead and show a moderate variation with the angle of incidence. Calculations by Whitehead for a typical planoellipsoidal lens show that substantial curvature of the wavefront occurs at the aperture when the feed element is at the focal point but that the wavefront may be made almost plane by moving the element slightly away from the focal point.

The just-described data for perpendicular polarization incident on a set of parallel plates apply equally well to an array of thin-walled square or rectangular tubes (see Figure 18-11*b*). However, for parallel polarization the constraint offered by the array of tubes has a large effect on its reflection characteristics. Wells²³ shows that, at the angle of incidence for which the diffracted wave first appears, a sharp peak of specular reflection also occurs.

Methods of Reducing Reflection Losses

Within the angle-of-incidence range given by Eq. 18-1 and Figure 18-12, the reflection from the surface of a metal-plate or waveguide lens may be canceled through the introduction of an additional reflecting discontinuity. Possible structures are shown in Figure 18-14, where in *a* a dielectric sheet is placed outside the lens and in *b* obstacles are placed inside the lens. In both cases the magnitude and phase of the additional reflection are adjusted to cancel the reflection from the plates. The magnitude depends upon the dielectric constant and the thickness of the dielectric sheet or the shape and size of the obstacles, while the proper phase relationship is obtained through choice of the spacing of the dielectric sheet or obstacles from the plate edges. The correct design for a given lens may be obtained experimentally; however, a theoretical design may also be computed through the use of graphical and tabulated data given by Lengyel²⁰ for the magnitude and phase of the reflection coefficient of the boundary.

FIGURE 18-14 Techniques for reducing surface reflections from metal-plate lenses

In a practical lens design, it is difficult to avoid the ranges of θ_i for which diffracted waves occur. Many early designs of metal-plate lenses did not do this, and thus considerable loss of gain resulted. One method of avoiding this condition, as may be seen from Figure 18-12, is to reduce the plate spacing; however, this reduces n and increases the reflection loss at angles near normal incidence and reduces the bandwidth. A further possibility is to fill the regions between the plates with dielectric material or to introduce ridges in the waveguide parallel to the axis (see Figure 18-14b) in a manner analogous to ridge waveguide.^{24,25} In this way, the plate spacing may be reduced to a point at which diffraction is no longer a problem while n remains at a reasonable value.

Another method of avoiding diffracted waves in one plane is to use a staggered arrangement of waveguide channels,²³ as in Figure 18-14c, now a proven technique in space-fed phased arrays. The spacing between scattering edges is effectively cut in half, thus doubling the frequency at which a diffracted wave first appears. This staggered arrangement also eliminates the sharp peak of specular reflection that occurs with the nonstaggered array of tubes for parallel polarization.

18.6 WAVEGUIDE LENSES

Three-dimensional unzoned waveguide lenses of the type shown in Figure 18-7a have been designed. The inner surface is an ellipsoid of revolution about the lens axis, and the outer surface is a plane perpendicular to the axis. One such lens²⁶ has a 36-in (914-mm) diameter and a 31.2-in (792-mm) nominal focal length and is constructed of 0.68-in- (17.3-mm-) inside-diameter square waveguide to provide a nominal $n = 0.5$ at 10 GHz. The lens was fed with a circular-aperture-waveguide horn that produced circular polarization. The reference has a number of plots of experimental data: gain, beamwidth, n , and focal length versus frequency; gain, beamwidth, and first sidelobe level versus feed-horn diameter; radiation patterns as a function of beam-scan angle; and gain, beamwidth, and first sidelobe level versus beam-scan angle. The sidelobe level increases from -22.5 dB at 13° beam scan and remains at about that level for beam scan to 22° . The gain decreases by 3 dB (from the on-axis value of 36 dB) at a beam-scan angle of 18° , or 7.65 beamwidths.

Another design²⁷ has a 24-in (610-mm) diameter and a 36-in (914-mm) focal length constructed of $^{5/}_{32}$ -in (4.0-mm) cell honeycomb to provide an $n = 0.642$ at 55 GHz. Because the honeycomb cells deviated from perfect hexagons, the performance varied with the linear-polarization orientation. The aperture efficiency was only 18.3 percent because random variations in the cell size produced large aperture phase variations.

To obtain wide-scan-angle performance, Ruze²⁸ investigated bifocal cylindrical constrained lenses in which the two focal points are equally displaced from the lens axis at P_1 and P_2 , as shown in Figure 18-15. The inner surface is found by equating optical-path lengths for the central ray and a general ray from each of the focal points. It is an ellipse, with foci at the two focal points, independent of n or lens thickness, given by

$$(x + af)^2 / (af)^2 + y^2 / f^2 = 1 \quad (18-4)$$

where $a = \cos \phi$. Imposing the two focal points uses two of the three degrees of freedom available. Ruze considered several alternatives for choosing the third condition: constant n , constant thickness, linear outer surface, third correction point, and no second-order error; for the last four, n varies with y . The deviations from a linear phase front for a general feed point were expanded into a power series and examined for each case. For the on-axis feed point there are no odd-order terms, and the second-order deviation (defocus) can be corrected by moving the feed point along the axis; however, this correction is not needed for all cases. The feed arc is chosen as a circle through the corrected on-axis feed position and the two focal points. Several of these designs permit a beam scan of 110° for $\phi = 50^\circ$. Feed-arc selection for reduced phase errors is discussed in Peebles²⁹ and in Rappaport and Zaghloul.³⁰

The constant- n lens has been the most popular. The thickness is given by

$$d = d_0 + (m\lambda + ax) / (n - a) \quad (18-5)$$

where m is the number of wavelength steps in the outer surface. Proctor and Rees³¹ analyzed this type of lens with results near those of Ruze. The constant- n lens was expanded to three dimensions by Fine and Reynolds;³² the inner surface is an ellipsoid of revolution about the

FIGURE 18-15 Bifocal metal waveguide lens

line through the focal points, and the outer surface is an ellipsoid with unequal principal radii. The performance is well behaved for feed points between the two focal points, but performance deteriorates rapidly for feed points beyond the focal points. Performance also degrades rapidly as the feed point is moved away from the xy plane.

A constant- n lens was used in an application³³ for which the scanning feed system was most conveniently designed for a planar feed aperture. The phase errors were minimized for the on-axis feed point by a method of stepping the outer surface. A constant- n lens was also used for a satellite antenna,³⁴ but with the two correction points collapsed to a single on-axis point so that the inner surface was a segment of a sphere and the outer surface a segment of a spheroid. The effects of zoning the outer surface were computed. The radiation-pattern effects of zoning were also computed in Lu.³⁵

A linear-outer-surface two-dimensional lens between parallel plates was constructed³⁶ for an X-band multibeam application by milling waveguides of unequal width (to obtain variable n with y) in metal blocks. The lens had good performance, and the tolerances obtained appeared sufficient to permit this technique to be used for frequencies up to 40 GHz.

Waveguide lenses have been designed to provide a larger bandwidth by designing for equal time delay^{37,38} for all rays through the lens. The phase delay in each waveguide is adjusted with a phase shifter to provide a planar wavefront. These lenses have a spherical inner surface so that they satisfy the Abbe sine condition for off-axis performance. Dion³⁸ has both single- and dual-frequency designs that obtain bandwidths that vary from 40 to 20 percent for lens diameters from 20 to 100 wavelengths.

18.7 BOOTLACE-TYPE LENSES

Bootlace lenses can have four degrees of freedom that permit designs with four focal points to obtain wide-angle performance for either multiple simultaneous beams or a scanning beam; however, most designs fix the outer surface and have three focal points. These constrained lenses have radiators on the inner and outer surfaces connected by TEM-mode transmission lines (usually coaxial or stripline), which give the appearance of untightened bootlaces, hence the name. Typically, all rays in these lenses have equal time delays from a focal point to the corresponding linear wavefront, and therefore they are inherently broadband, limited only by component bandwidths and the performance of a fixed aperture size.

Gent³⁹ identified most of the useful properties of this type of lens, including (1) four degrees of freedom, (2) the fact that one surface may be displaced and/or rotated relative to the other (i.e., the surfaces may have independent coordinate systems), (3) the ability to add phase shifters, attenuators, and/or amplifiers in the lens transmission lines to provide outer-surface aperture illumination control and beam scan, (4) the fact that the line lengths can be stepped by multiple wavelengths, analogously to the physical stepping shown in Figure 18-2 without creating shadowing but with reduced bandwidth, (5) the ability of radiators on the two lens surfaces to have different polarizations, and (6) the fact that the spacing between aperture radiators must be less than $\lambda/(1 + \sin \theta_{\max})$ to avoid grating lobes, where θ_{\max} is the maximum beam-scan angle from the aperture normal.

The Rotman-Turner⁴⁰ lens is a two-dimensional bootlace lens with a linear outer surface perpendicular to the lens axis and three focal points, one on axis and two equally displaced from the lens axis, shown in Figure 18-16 as points $G(-g, 0)$, $F_1(-\cos \phi, \sin \phi)$, and $F_2(-\cos \phi, -\sin \phi)$, respectively, where central rays from F_1 and F_2 subtend an angle ϕ with the axis. Desired wavefronts are displaced from the vertical by angles 0 , ψ , and $-\psi$, respectively, where $\psi = \phi$ in this design. All dimensions are normalized to the F_1 -to-origin distance. Pairs of inner- and outer-surface radiators are connected by coaxial lines with the general pair located at $P(x, y)$ and $Q(t, u)$, respectively. Let $w = s - s_0$ be the normalized

Also shown are lens shapes for four values of g . For $\phi = 30^\circ$ and $g = 1.137$ (the optimum value of g for $\phi = 30^\circ$), the normalized path-length error is <0.00013 for $-0.55 \leq u \leq 0.55$ (i.e., aperture $= 2u_{\max} = 1.10$ and $g/2u_{\max} = 1.035$). If a phase error of $\pm\lambda/8$ is allowed, an aperture of 1000 wavelengths can be used to obtain a beamwidth $<0.075^\circ$ that can be scanned more than 60° , or more than 800 beamwidths.

An experimental lens at 3.0 GHz with $\phi = 30^\circ$, $g = 1.137$, $u_{\max} = 0.6$, and $D/\lambda = 18$ was constructed⁴⁰ by using RG-9/U coaxial cables for the lens, a TEM-mode parallel-plate structure between the feed position or positions and the inner lens surface, a flared parallel-plate aperture that contained the linear outer surface, and quarter-wavelength probes into the parallel-plate regions.

The Archer lens⁴¹ is a Rotman-Turner lens with additional features: (1) The parallel-plate region between the feeds and the inner surface is filled with a dielectric material of relative dielectric constant ϵ_r to reduce all linear dimensions by a factor of $n = (\epsilon_r)^{1/2}$, thereby permitting its use in a smaller volume. (2) Stripline or microstrip lens and feed-port connecting lines are printed on an extension of the dielectric material, thereby removing connectors and probes and the associated mismatches and permitting constructions to tight tolerances and wide-bandwidth operation. (3) The beam angle ψ can differ from the feed angle θ so that $\sin \psi / \sin \theta = K$ (where $K = 1$ for the Rotman-Turner lens)⁴²; $K > 1$ permits obtaining large beam-scan angles with practical feed positions, and $K < 1$ permits reduction of the lens size for limited scan-angle applications. These features increase the lens versatility, but do not increase the design degrees of freedom.

There is a nomenclature difference between the Archer and Rotman-Turner lenses. In the Archer lens, the printed-circuit lines that form the lens appear to be just connecting lines, while the dielectric region between the feed ports and the inner surface appears to be a lens and is usually referred to as such.

Archer lenses⁴¹ have been designed and constructed with materials with ϵ_r 's from 2.5 (Teflon fiberglass) to 233 (cadmium titanate). Figure 18-17 shows a 20-radiator, 16-beam lens constructed in microstrip on a barium tetratitanate ceramic substrate with $\epsilon_r = 38$. Most designs have a beam coverage of 120° , range from a 4-radiator, 4-beam lens to a 140-radiator, 153-beam lens, and have a typical operating frequency band of almost two octaves. Designs usually have adjacent beams overlap at the 3-dB points (with feeds at

FIGURE 18-17 Archer lens, $\epsilon_r = 38$

equal intervals in sine space) at the maximum operating frequency where the gain and beamwidth are consistent with that obtainable from the full aperture. At lower frequencies, the beams broaden and overlap at a higher level, and gain decreases more rapidly than the beamwidth broadening would indicate owing to beam-coupling loss. Low sidelobe patterns⁴³ are obtained by feeding several adjacent beam ports with weighted amplitudes.

Alternative designs⁴¹ are obtained by fixing the outer surface as a circle, with an arc up to 60° , that is more adaptable to conformal applications. A circular aperture eases the design problem of eliminating aperture resonances that are common in linear arrays, increases the beam coverage with reduced gain roll-off with off-axis beam scan traded against on-axis gain, and reduces the effects of outer-surface mismatch since reflections do not have a constant phase difference from radiator to radiator as with a linear array.

The linear-aperture bootlace lenses discussed earlier produce fan beams. Multiple pencil beams in a plane can be produced by illuminating a parabolic-cylinder reflector⁴⁰ or cylindrical lens (see Figure 18-1) with the linear aperture. A two-dimensional cluster of pencil beams may be formed⁴¹ by stacking vertical linear-aperture lenses, so that the outer surface of each lens provides a column of radiators, and by feeding the beam ports of these lenses with the output ports of a stack of horizontal lenses. The beam ports can be used separately, adjacent beam ports may be combined to provide monopulse-type outputs, and multiple beam ports may be combined after weighting to provide low sidelobe beams. Three-dimensional bootlace-type lenses are discussed in Gent,³⁹ Archer,⁴¹ and in other literature.⁴⁴⁻⁴⁷

Gent³⁹ found a special case of the two-dimensional bootlace lens that has feed points and the inner surface on a circle of radius R and the outer surface on a circle of radius $2R$ with equal line lengths between the inner- and outer-surface radiators and recognized that it is equivalent to the R - $2R$ geodesic scanner.^{48,49} It is proved in Kales and Brown⁵⁰ that the R - $2R$ bootlace lens is unique. Bootlace R - $2R$ lenses have been constructed⁴¹ by using printed-circuit techniques on dielectric materials. The R - $2R$ type lens has been extended into an R - KR lens,⁴¹ shown in Figure 18-18, that has equal radial line lengths between radiators on a circle of radius KR and radiators on a circle of radius R . With $K = 1.92$, the optimum value, it is the printed-circuit version of a constant-index lens. It provides a nearly linear wavefront for an arc of

FIGURE 18-18 R - KR -array geometric relationship

approximately 120° on the circle with radius R . By adding a circulator in each of the lines to permit feed inputs, beams covering 360° can be obtained simultaneously.

18.8 PHASED-ARRAY LENSES

Phased arrays are discussed in Chapter 20; in this section space-fed phased-array lenses are discussed for comparison with other lenses.

Space-fed arrays⁵¹⁻⁵⁷ have constrained lenses that usually are constant-thickness^{51,54} with planar surfaces. Elements (or modules), usually perpendicular to the surfaces, contain inner- and outer-surface radiators, phase shifters, and in some cases other components such as phase-shifter drivers and polarization switches. The inner-surface radiator has the polarization of the feed or feeds and needs to be matched only for the incidence angles from the feed or feeds. The outer-surface radiator can have any polarization or polarizations that may be switchable, must be matched for the range of beam-scan angles used, and must withstand the environment. Most phase shifters are digital, modulo 360° , in which the number of bits is determined by the required beam-pointing accuracy and sidelobe levels. Either diode- or ferrite-type phase shifters are used, the type for a given application being determined by the operating frequency, radio-frequency power levels, required phase-state-switching speed, and switching and/or phase-state-holding power.

Beam steering and collimation (the conversion of the feed wavefront to a plane wave) are obtained by the phase shifters; the computed phase shifts required for the two functions are superimposed. The phase shift required for collimation is determined from ray tracing as for other lenses. Phase-shift commands may be computed and commanded on an element-by-element basis or by rows and columns.⁵² This collimation method reduces the number of phase-shifter bits required to obtain a given beam-pointing error, since the otherwise-present regularity of phase errors over the lens outer surface is destroyed.

In many pulsed-radar applications, it is possible to change the state of the phase shifters between transmit and receive; in these cases, separate transmit and receive feeds may be used. If sufficient isolation between feeds is obtained, the need for a transmit-receive switch is eliminated. In addition, separate feeds permit the lens illumination to be optimized for both transmit and receive; e.g., to obtain maximum gain on transmit and low sidelobes on receive.

For applications that require large beam-scan angles and large instantaneous-frequency bandwidth, lenses permit the total angular coverage to be divided into sectors, each with a separate feed, to obtain more nearly equal time delay for all beam positions. The feeds may be used to obtain simultaneous beams,⁵³ or one feed may be selected by a switching network.

Some applications of space-fed-array lenses are discussed in the literature.⁵⁴⁻⁵⁷

18.9 DOME ANTENNAS⁵⁸⁻⁶⁵

The dome antenna was developed to obtain an antenna to scan a beam over a full hemisphere or more for hemispherical-coverage applications as an alternative to the three or four planar arrays usually considered.

In its simplest form, the dome antenna (see Figure 18-19) has a constrained constant-thickness lens (the dome) fed by a planar array, both symmetric about the vertical axis. The technique is to illuminate an aperture (a portion of the dome) that has an appreciable area perpendicular to any of the desired beam directions to obtain antenna gain in those directions. The feed array can produce convergent or divergent rays to illuminate the required

FIGURE 18-19 Dome-antenna nomenclature

lens area. The lens has a phase-delay gradient in the elevation plane to refract rays in the θ' direction when fed at an angle θ . $K = \theta'/\theta$ is defined as the scan amplification factor.

The dome is constructed of modules normal to the surfaces which have radiators on each surface connected by transmission lines that contain the required phase delay. The phase delay could be provided by switchable phase shifters,⁵⁸ but in practice this method is too expensive, so fixed delays are used. There are a number of methods for implementing the delays; in one module configuration,⁵⁹ the lengths of two dielectric-filled circular waveguides of different diameters in series are varied to obtain the phase delay in 20° increments. The modules may have phase delays modulo 360° (with a bandwidth penalty) and have different polarizations on the two lens surfaces. The spacing between modules must be small enough to suppress grating lobes.

Phase delays are generally equal in all modules that have the same cone angle θ . There are several design techniques for determining dome-module phase delays. Since the dome is in the near field of the feed array, ray-tracing methods may be used. For a hemispherical dome of radius R and a constant $K \neq 1$, one technique⁵⁸ equates the path lengths for rays from the center of the feed array at angles θ and $\theta + d\theta'$ and, after integrating, obtains the required phase delay, which is $(2\pi/\lambda) R [1 - \cos(\theta' - \theta)]/(K - 1)$. For these fixed phase delays, rays from the desired planar wavefront are traced through the lens to the feed array to determine the required feed-array wavefront, which in general is not planar. The gain (relative to the feed-array broadside gain without a dome) of an antenna designed in this manner is shown in Figure 18-20 for several values of K . It is evident that beam angles greater than 90° can be obtained for $K > 1$ and that maximum gain occurs for beam angles $\theta' > 90^\circ$ for $K > 2$.

It is desirable to be able to design for prescribed antenna gain versus θ' profiles as, for example,⁵⁸ that shown in Figure 18-21. For some applications, it is also helpful if the dome has an elongated shape along the axis; i.e., the dome is a cylinder generated by a noncircular arc. For these cases, the lens-module phase delays can be designed⁵⁸ by allowing a variable K with θ and applying the techniques used for designing a shaped-beam reflector (see Silver,² pages 497–500).

FIGURE 18-20 Dome-antenna relative gain versus θ' as a function of K

FIGURE 18-21 Typical gain versus θ' profile for a dome antenna

These techniques have been implemented⁵⁹ at C band with a 4-ft- (1.2-m-) diameter hemispherical dome composed of 3636 modules (dielectric-loaded circular waveguides with a phase-delay increment of 20°) and an $F/D = 0.75$, space-fed planar phased array with 805 elements. Dome loss was less than 1 dB over a 10 percent frequency band. Two gain-versus-scan-angle-profile designs were measured. One version with $K < 2$ with maximum gain at approximately 60° had peak sidelobes below -18 dB and average sidelobes below -25 dB. It had a 13 percent bandwidth for a zenith beam and a 6.3 percent bandwidth for a 60° beam position. The gain profile matched predictions within 0.3 dB for scan angles up to 60° . Another version with $K = 2.6$ with maximum gain at 110° demonstrated good performance in a limited amount of data. Another implementation,⁶⁰ also at C band, had a hemisphere on a cylinder dome 76 in (1.93 m) in diameter and 51 in (1.30 m) high that had 8511 modules, each a thin-walled metal tube that contained a serrated cruciform to provide the phase delay in increments of 20° between modules. The feed array was 47 in (1.19 m) in diameter and used 1120 elements. The gain profile had maximum gain at $\theta' = 90^\circ$.

An alternative to a constrained lens is the use of a graded-thickness (in elevation) homogeneous dielectric material with quarter-wavelength matching layers on each surface.^{58,65} Several techniques for designing to desired gain versus scan-angle profiles and for determining limits on attainable profiles have been analyzed.⁶¹⁻⁶³ A two-dimensional antenna with $K = 1.5$ that used a concave-outer-surface Archer lens for the feed has been analyzed⁶³ and measured⁶⁴; it improves the wide-scan-angle sidelobes, operates over a frequency band of more than an octave, and can provide multiple simultaneous beams.

18.10 LUNEBURG LENSES

Luneburg⁶⁶ investigated a class of spherically symmetric, variable-index-of-refraction n lenses that image two concentric spheres on each other. The *Luneburg lens* is a special case of this class in which one sphere has an infinite radius and the other is the lens surface. For a unit-radius lens, the n as a function of the radius r is $n = (2 - r^2)^{1/2}$. When fed at a point on the surface, it produces a plane wavefront, and by moving the feed on the surface, beam

scan over all space can be obtained (if the presence of the lens support and feed-scanning mechanism is ignored). The scanning applications and many design principles of Luneburg lenses are discussed in Chapter 18.⁶⁶

A number of authors^{67–75} have extended Luneburg's work. References 67–70 derive small-feed-circle lenses in which the feed radius is smaller than the lens radius. References 70–74 consider variations that include conical and beam-shaping wavefronts in addition to the plane wavefront. Cheng⁷⁵ considers a design to use a defocused feed.

Luneburg-lens radiation-pattern computations have been considered by most of the Luneburg-lens authors and in particular by Jasik⁷⁶ and Braun.⁷⁷ The Luneburg-lens aperture illumination is the feed pattern times $\sec \phi$, where ϕ is the feed-pattern angle. The increase in energy density near the aperture edges produces (relative to other lenses) high gain and small beamwidths and limits the sidelobe levels to -17 to -18 dB.

Early Luneburg lenses were two-dimensional (or cylindrical) slices through the center of the sphere because techniques were not available for constructing a sphere. One model⁷⁸ was a 36-in- (914-mm-) diameter lens constructed of almost parallel plates filled with polystyrene that operated in the TE_{10} mode at X band. The plate spacing was $a = \lambda/[2(\epsilon_r - 2 - r^2)^{1/2}]$, where ϵ_r is the dielectric constant of the filler material and r is the normalized radius. In addition to the aperture-edge energy increase, two-dimensional Luneburg lenses produce a saddle-shaped wavefront because of the circular aperture. This can be corrected by adding to the aperture parallel plates with a linear aperture, but this limits the beam-scan angle. Calculated and experimental radiation patterns show about -17 -dB sidelobes in the E plane and a flat-top pattern in the H plane. Jones⁷⁹ constructed an air-filled, almost parallel-plate TE_{10} -mode lens. Walter⁸⁰ constructed surface-wave lenses with tapered-thickness dielectric on a ground plane, metal posts on a ground plane, and a "holey-plate" structures.

The symmetry of the Luneburg lens can be exploited by adding planar reflectors through the lens center to obtain a virtual-source antenna.⁸¹ This permits eliminating large segments of the lens to reduce weight and allows the lens to be supported more easily, but it introduces aperture blocking by the feed.

Spherical Luneburg lenses have been constructed by using several techniques. Crushed Styrofoam⁸² was used for a 24-in- (610-mm-) diameter lens. Expandable polystyrene beads,^{83–85} expanded and solidified in heated hemispherical molds, were used for a 10-step, equal- ϵ_r increment, 18-in- (457-mm-) diameter lens. Webster⁸⁶ provides performance of a 10-step Styrofoam 18-in- (457-mm-) diameter lens. Foamed glass⁸⁷ was used to fabricate a 10-step 12-in- (305-mm-) diameter lens to obtain high-power operation. Calculations⁸⁸ of the heat distribution in a Luneburg lens indicate that the feed region reaches the highest temperature under high-power operation. A ray-tracing method for checking the design of a stepped- n Luneburg lens is provided in Mathis.⁸⁹

An important use of the Luneburg lens is as a reflector,^{85,90} obtained by placing a reflecting cap on the lens surface. An incoming plane wave is focused at a point on the cap and reflected; after transit through the lens the second time, it is a plane wave propagating in the opposite direction. The angular extent of the cap is chosen as a compromise between obtaining wide-angle performance and minimizing partial blockage of incoming rays by the cap.

For many applications that do not require the performance of a Luneburg lens, the literature^{91–95} investigates the performance of constant- n spherical lenses that are more easily constructed than Luneburg lenses.

Another class of two-dimensional Luneburg lenses is the geodesic lens, composed of a pair of nonplanar metal plates spaced a constant distance apart with a spacing small enough so that only a TEM mode can propagate. Myers⁴⁹ proved that rays in this medium follow geodesic paths on the mean surface. Rinehart^{96,97} derived the surface shape that is required for a two-dimensional Luneburg analog whose edge has a tangent normal to the aperture plane. Warren and Pinnell^{98,99} derived surfaces with the edge tangent parallel to the aperture plane.

Kunz¹⁰⁰ generalized the analysis and described several designs. Rudduck et al.¹⁰¹⁻¹⁰³ describe small-feed-circle design and also designs that radiate at a displaced angle from the aperture plane. Johnson¹⁰⁴ provides an excellent summary of geodesic lenses and distinguishes between tin-hat, helmet, and clamshell types. Hollis and Long¹⁰⁵ describe a feed-scanning implementation for limited beam-scan angles with a geodesic Luneburg lens. Johnson¹⁰⁶ shows radiation patterns of a 24-in- (610-mm-) diameter, 4.3-mm- λ lens with extension plates to a linear aperture that provides a total beam scan of 60°. The beamwidth is 0.5°, and sidelobes are below -25 dB for most beam positions. Johnson¹⁰⁷ demonstrates that any two-dimensional lens can have a geodesic analog.

18.11 FRESNEL ZONE PLATE LENSES

Lens antennas called *Fresnel zone plates* can be constructed in a planar form. They have the advantages of reduced weight, lower ohmic loss, and ease of construction compared with the conventional dielectric lenses shown in Figure 18-1. A Fresnel amplitude-zone plate lens consists of alternating opaque (metal) and transparent (dielectric) rings with the radii determined by the zone number. Measured results show that the beamwidth from these lenses is comparable with that obtained from a paraboloidal reflector of the same size but that the gain is about 15 dB less.¹⁰⁸ Fresnel phase-zone plate lenses are constructed by cutting annular rings in a flat piece of dielectric or by utilizing concentric rings of different dielectric materials of the same thickness.¹⁰⁹ Phase-zone plate lenses do not suffer the inefficiency of amplitude-zone plate lenses because the former are completely transparent.

19.1 INTRODUCTION

There has been continuing interest in designing a UWB antenna that operates over a wide frequency range and that can be used for multiple channels or systems. Regulatory restrictions on bandwidth and the greater technical challenges and cost involved in developing a UWB antenna, as well as the corresponding operating systems, have largely limited the development of UWB antennas to special research organizations and agencies in military applications. A recent FCC ruling allowing the operation of UWB signals in various sensing, imaging, and communication applications has once again revived interest in designing UWB antennas and in their potential applications. Technology advances in high-speed analog-to-digital and digital-to-analog devices, digital frequency synthesis, and digital receivers also allow for rapid and low-cost implementation of UWB systems below 3 GHz. Therefore, more attention is now being given to designing compact and low-cost UWB antennas.

The term *UWB* has often been used loosely. The original FCC definition of UWB specifies 25 percent or more fractional bandwidth. That is the ratio of a signal's -10 -dB bandwidth to center frequency. In this chapter, *UWB* mainly refers to a bandwidth of more than 2:1. That is the ratio of the highest frequency to the lowest frequency of the -10 -dB bandwidth. Some people determine the antenna's bandwidth based on the frequency range where the return loss (or reflection coefficient) level is less than -10 dB. However, note that a low return loss does not necessarily imply a strong radiation. Nor does it say anything about the radiation pattern. The return loss value has even less meaning if the antenna contains absorptive mechanisms. Since the main function of an antenna is to radiate sufficient energy in desired directions, it makes sense to use realized gain and radiation pattern to define the bandwidth.

There are many theories and examples of UWB antenna designs. The literature also offers many detailed discussions about design procedures and the parameters of these designs. Unfortunately, many of them fall short of providing physical insights about antenna operations and wave behaviors. Modern powerful computation capability seems to turn more antenna designers into antenna optimizers who seek to rely on massive computation power to come up with an "improved" or "optimized" antenna design. No doubt, this approach is indeed attractive to young antenna engineers who have not yet developed a good physical understanding of antennas, especially for complex antennas, but who have modeling tools and experience. Therefore, it is not the intention of this chapter to discuss various specific UWB antenna designs; there are already many great discussions in other chapters of this Handbook. Rather, this chapter attempts to simplify discussions by focusing on the fundamental principles and formations of UWB antennas to promote a better physical understanding of UWB antenna operations and to encourage the development of more new UWB antenna designs.

19.2 FUNDAMENTALS OF UWB ANTENNA DESIGN

Before we discuss the principles of designing a UWB antenna, it is essential to review the phenomena of propagation, scattering, and radiation of electromagnetic waves since they will provide important clues to UWB antenna operations.

What Is Propagation of Electromagnetic Waves?

The propagation of electromagnetic waves is an iterative induction process of time-varying electric and magnetic fields, which is governed by the following equations in a source-free region:

$$\begin{aligned}\nabla \times \bar{E} &= -\frac{\partial(\mu\bar{H})}{\partial t} \\ \nabla \times \bar{H} &= \frac{\partial(\epsilon\bar{E})}{\partial t}\end{aligned}\quad (19-1)$$

For instance, Figure 19-1 illustrates that a time-varying electric field in a source-free region induces time-varying magnetic fields around it. These induced magnetic fields subsequently induce time-varying electric fields around them. This induction process continues and constitutes the electromagnetic propagation. Any change in the property of the medium where propagation is taking place causes electromagnetic scattering. Such scattering could be in the form of reflection, refraction, or diffraction and depends upon the type of change involved, as illustrated in Figure 19-2. It is helpful to understand such scattering behaviors while designing a UWB antenna since an antenna can be considered as a scattering structure strategically positioned near an excitation source. The total radiated field is then the sum of the unperturbed incident field \bar{E}^i and the scattered field \bar{E}^s , that is, $\bar{E} = \bar{E}^i + \bar{E}^s$.

The properties (spectrum, pattern, amplitude, and phase) of the scattered fields depend on the geometry, composition, and orientation of the perturbation with respect to the incident fields.

What Is Electromagnetic Radiation?

Electromagnetic radiation is a phenomenon of unbounded propagation of electromagnetic waves. Radiation causes a net loss of electromagnetic energy from the source region (a region where electromagnetic energy is supplied). The total radiated power is calculated from total power flow away from an arbitrarily large closed region that contains sources, that is, $P_r = \oint_S \bar{E} \times \bar{H}^* \cdot d\bar{S}$.

What Is an Antenna?

There are many ways to define an antenna. Some consider an antenna as an impedance transformer between a transmission line and the open space. Others define an antenna as a coupler that transfers electromagnetic energy into space. Readers who use most antennas

FIGURE 19-1 The iterative induction process of electromagnetic propagations

FIGURE 19-2 Scattering of electromagnetic waves: (a) material changes and (b) geometry changes

made of good (or poor) conductors probably are used to thinking of an antenna as a current-guiding structure that somehow converts the conduction currents to displaced currents. It is probably better to consider an antenna as a single or plural near-field scattering structure that generates radiation by the strategic scattering of the incident fields produced by an excitation source. Under such considerations it is obvious that an antenna does not have to be made of conductors. Instead any materials that have the right properties for creating and controlling scattering can be used to design an antenna. Note that this is different from using materials as an additional loading. Rather, the material itself could be the primary component of the antenna structure. For instance, two UWB antenna examples discussed at the end of this chapter utilize a low-loss dielectric body as the main radiating structures. This understanding is important since many advanced current or future materials have unique properties that could be utilized for antenna designs.

It is also important to recognize that the difference between a transmission line and an antenna lies only in the amount of radiation generated, not in the geometry itself! For instance, an open-ended, two-wire “transmission line” can be an “antenna” if the spacing between the lines becomes large with respect to the wavelength such that the diffraction from the wires and wire ends do not cancel each other or the incident fields in the exterior region. For the same reason, a “horn antenna” may become just an open-ended “waveguide” if the aperture becomes small compared with the wavelength.

What Makes a UWB Antenna?

A UWB antenna is an antenna capable of producing a *similar radiation* (patterns and gain) over a very wide frequency range (more than 2:1 bandwidth). Although a wider bandwidth can be obtained by trading off impedance matching and realized gain, we will not consider this approach in this chapter. We will refer to the *realized gain*, $G = e(1-|\Gamma|^2)D$, as simply *gain* throughout this chapter. The variables e , Γ , and D represent antenna efficiency, input reflection coefficient (or return loss), and directivity, respectively. It should be cautioned that defining an antenna’s bandwidth based on return loss being lower than -10 dB is inadequate since it does not guarantee strong radiation in the desired direction(s). When an antenna contains absorptive materials, low return loss indicates low return and says nothing about radiation (gain, bandwidth, and pattern). UWB radiation can be accomplished via the following three approaches:

- I. Perturbing electromagnetic resonance to broaden the resonant peak
- II. Allowing only one dominant radiation region that is physically small compared with wavelengths
- III. Maintaining a “similar” radiation/scattering geometry (shape and dimension) in terms of wavelength

Herein, UWB antenna designs using the preceding *I*, *II*, or *III* approach will be referred to as Type-I, Type-II, and Type-III UWB antennas, respectively. It is unusual for Type-I UWB antennas to have more than 3:1 bandwidth. Type-II UWB antennas offer superior pulse response but may have low efficiency (if absorptive loading is applied) or frequency-dependent gain and patterns. Many Type-II antennas can achieve 9:1 bandwidth. Type-III UWB antennas offer frequency-independent gain and patterns but are often dispersive. The following sections will provide more analysis of these three types of UWB antennas.

19.3 TYPE-I UWB ANTENNA DESIGN

This type of UWB antenna achieves bandwidth by introducing incoherent resonance and effectively lowering the quality factor of the electromagnetic resonance. The majority of Type-I UWB antennas are variations of dipoles or monopoles.

Common Broadband Dipoles

The radiation of a thin-wire dipole is mainly from the superposition of the direct radiation (the incident field) from the feed and strong diffractions from the two ends. The magnitude and phase relationship between these diffracted fields with respect to each other and the direct incident field ultimately determine its bandwidth and pattern behavior, as illustrated in Figure 19-3a. The phase relationship is determined from the propagation delay from the feed to each end and then to a certain pattern direction. Notice that if the length, l , is short such that its propagation phase delay is insignificant, and if these diffractions are strong, they could jointly cancel the incident fields and result in weak radiation. This is indeed the case when the dipole is much less than half of a wavelength. Along the boresight, the interference between the incident and scattered fields is responsible for the narrowband and strong frequency-dependent gain and pattern behavior of the thin-wire dipole. It is well known that a bowtie dipole design has a much broader bandwidth compared with a

FIGURE 19-3 Comparison of the radiation/scattering of a thin-wire dipole and a bowtie dipole

thin-wire dipole. This is because of the involvement of more incoherent diffractions, as illustrated in Figure 19-3*b*, which shows four corner diffraction terms and two edge diffraction terms. Since not all diffractions have the same phase at a specific frequency and specific pattern angle, the total radiated fields exhibit a wider bandwidth. In fact, the wider the phase distribution of all contributing scattering terms, the wider the bandwidth. There are many other published 2D or 3D variations of dipoles¹⁻³ that showed bandwidths of up to 3:1. The upper frequency limit of this type of UWB antenna is usually limited by the excitation of higher modes that cause pattern narrowing and multiple radiation lobes.

19.4 TYPE-II UWB ANTENNA DESIGN

Type-II UWB antennas achieve wide bandwidth by controlling diffractions on antenna structures via careful geometry design or proper utilization of absorptive loading. Type-II UWB antennas often produce some degree of frequency-dependent gain and patterns because diffraction and absorption are functions of frequency.⁴ For instance, a curved section of an antenna may appear to be smooth for short wavelengths and produce less diffraction but would abruptly bend for long wavelength. Similarly, a section of tapered resistive loading could be a long and smooth tapering for short wavelengths but would be short and abrupt for long wavelengths.

Type-II UWB Antenna Using Absorptive Loading

Instead of trying to add multiple diffractions to achieve a wide bandwidth as in Type-I UWB antennas, Type-II UWB antennas aim to minimize diffractions. Absorptive loading is an effective way to achieve this goal at the price of lower antenna efficiency. Therefore, the art of absorptive loading is to utilize the minimum amount of absorptive treatment to reduce diffractions to acceptable levels. This would require some knowledge of the types and causes of dominant diffraction events. Both electric and magnetic absorptive materials have been used. Resistively loaded dipoles⁵⁻⁸ and resistively loaded horns⁹ are well-known examples. Although the low efficiency can sometimes be compensated for by means of higher input power, caution needs to be exercised to take care of the heat produced by the absorptive loading.

Type-II UWB Antenna Using Curved Arms

Another way to reduce the diffraction effect without utilizing absorptive loading is to control diffractions by properly shaping antenna geometry to avoid strong localized diffractions, which usually arise from abrupt discontinuities. Instead, gentle and continuous diffractions are allowed to take place along the whole curved arms (see Figure 19-4). The low-frequency limit of this design occurs when the arm length is less than half of the wavelength. With such a short length, the curvature becomes ineffective, and significant diffractions arise at the ends of antenna arms. The high-frequency limit is determined by the pattern distortions caused

FIGURE 19-4 Smooth diffraction control using curved arms

by the curvature smoothness and the starting curvature. A properly curved antenna arm could increase the -10 -dB return-loss bandwidth to 9:1. However, such a design often exhibits frequency-dependent gain and pattern. Typically, the resultant boresight gain increases with frequency and beamwidth decreases with frequency. Common examples of Type-II UWB antennas include tapered-slot antennas,^{10–12} rolled-edge horns,^{13,14} and ridged horns.^{15–17} Of course, both curved-arm and absorptive loading can also be applied simultaneously to further reduce antenna size and to achieve a better pattern stability at the expense of antenna efficiency.⁹

19.5 TYPE-III UWB ANTENNA DESIGN

Type-III UWB antennas are probably the most widely used UWB antennas. This type of antenna adopts frequency-independent or frequency-scaled geometries. Among them, angle-defined geometry, complementary geometry, and log-periodic geometry^{18–20} are the best known. Although these geometries could be good candidates for designing a frequency-independent or UWB antenna, employing these geometries alone does not necessarily produce a UWB antenna design. Other antenna design considerations such as feeding scheme, mutual coupling, and truncations must be taken into account. This section discusses some basic guidelines that should be helpful in designing or optimizing a Type-III UWB antenna, which is characterized by its frequency-independent radiation characteristics such as gain, patterns, and impedance.

- **Frequency-Scaled Radiation Structure** Considering the far fields radiated from a local one-dimensional distribution of electromagnetic fields of equivalent currents:

$$\vec{H} = \nabla \times \left(\hat{x} \frac{e^{-jkr}}{4\pi r} \int_{-a_e}^{a_e} J(k_x, x') e^{jk_x x'} dx' \right) = D \frac{e^{-jkr}}{4\pi r} F(k_x a_e) \quad (19-2)$$

$$2a_e : \text{effective aperture size}; \quad k_x = k \sin \theta = \frac{2\pi}{\lambda} \sin \theta$$

the effective aperture area is the region where most in-phase radiations (at a given frequency) occur. From Eq. 19-2, if $J(k_x, x') \approx J(k_x x')$ and $a/\lambda \approx \text{constant}$, the radiated fields should be independent of frequency. That is, as frequency varies, the equivalent current distribution should be scaled in proportion to the wavelength.

- **Effective Radiation from Active Regions** At a given frequency, the antenna should form a region where all radiations are in phase and in the same polarization at any instant. Note that the phase and polarization of the radiated field could vary with time as in the case of circularly polarized antennas. Such a region is commonly called an *active region*. However, this terminology is somewhat misleading since radiation also occurs outside the active region. But the contribution of radiation from outside the active region is negligible in the far field because of cancellation or because it is too weak. Figure 19-5a shows a log-periodic dipole array (LPDA) and the active region where the currents on adjacent dipole elements become in phase at a given frequency and at any time. The location of the active region is related to the phase variation along the feeding transmission line also illustrated in Figure 19-5a. To increase radiation, the elements in the active region should also be at resonance. A strong radiation from the active region is very important in designing a Type-III UWB antenna because it ensures rapid energy attenuation after passing through the active region. Otherwise, frequency-dependent gain,

FIGURE 19-5 (a) Illustration of a time snapshot current direction and feeding-line phase on a log-periodic dipole array at a given frequency; (b) A time snapshot of the phase associated with fields on the arms of a circular Archimedean spiral antenna at a given frequency

pattern, and impedance could occur due to radiation from higher-order modes or from the ends of the antenna structure. Similarly, Figure 19-5b plots the instantaneous phase of the fields along a circular Archimedean spiral antenna at a given frequency. A broad active region can be clearly identified by its relatively slow phase variation. Note that although the left and right sides of the active region appear to be out of phase, the radiated fields are actually in phase since the current flows in opposite directions. Therefore, this active region radiates linearly polarized fields similar to a one-wavelength circular ring at any given time. As time progresses, the fields in the active region rotate and produce circularly polarized radiations.

- Strong Coupling Between Adjacent Modes** Continuous and stable antenna characteristics across an ultrawide bandwidth require a smooth transition from one active region to the next as frequency varies. This implies a strong coupling between adjacent structures. In the case of a spiral antenna (see Figure 19-5b), this requires a sufficient winding tightness (or lower growth rate) to avoid under sampling the phase variations in the active region. Such an under sampling causes undesired fluctuations in gain, pattern, and impedance.
- Excite from Highest Frequency End** Since an electrically large structure could support undesired higher modes, the antenna should be fed from the high-frequency region (small resonant structures). This region will be too small to support a resonance, so most of the lower-frequency energy will simply pass through to the larger structures.
- Active Region Transition Scheme** Consider a UWB antenna that is formed by assembling structures with similar geometry but which are scaled with distance from a reference feedpoint, as illustrated in Figure 19-6. Now, let's think about how the active region should migrate with frequency. Figure 19-7 reveals two possible schemes, *A* and *B*, with the shadowed region being the active region. At the highest frequency (leftmost figures), the active region is located near the center, where the feed is. As frequency decreases (middle figures), the active region in scheme *B* expands and encompasses the previous active region at a higher frequency. Although the "area" of the active region in the *B* scheme appears to be scaled with

FIGURE 19-6 Distance-scaled structures

FIGURE 19-7 Different schemes of active regions: (a) Both the aperture size and structure are scaled with frequency. (b) Although aperture size is scaled with frequency, the structure is not.

wavelength, the structures within the active region are not. As frequency decreases, more and more structures are included in the active region and give rise to different antenna characteristics. On the other hand, the active region in the A scheme migrates outward and the structures in the active region are similar but scaled proportionally to the wavelength. Therefore, the A scheme is truly a frequency scaled design and should be adopted for UWB antenna designs. Note that the active region may or may not overlap the previous one as frequency varies. This depends on the design and the frequency step. Recall that the antenna is fed from the high frequency region, and there is strong mutual coupling between adjacent structures. To achieve scheme A, a special arrangement is necessary to reduce low-frequency radiation in high-frequency regions. Good examples can be found in the LPDA and spiral antenna designs shown in Figure 19-5. In the LPDA, the feeding polarity of the adjacent dipoles is reversed such that radiation from them is canceled at low frequencies where the phase delay from the length of these electrically short dipoles is negligible. In the two-arm spiral case, the adjacent arms in the high-frequency region are out of phase at low frequencies because the two arms are fed with 180° phase difference and the phase delay from the half-turn path difference is negligible at low frequencies. Another simpler way would be to simply bend the antenna arm back and forth as in the sinuous antenna case. More examples of Type-II UWB antennas can be found in Chapter 17.

19.6 THE DUAL-POLARIZATION UWB DIELECTRIC ROD PROBE (DRP) ANTENNA

Introduction

It is well known that a homogeneous dielectric rod can be used to guide electromagnetic waves. Unlike metallic waveguide, the lowest mode of a dielectric-rod waveguide (HE_{11} mode) does not have a cutoff frequency. As wavelength increases, more energy is

guided outside the rod. Most of the energy is guided inside the rod when the rod diameter becomes greater than the guided wavelength. This adaptive field distribution as a function of frequency makes a dielectric rod a good candidate for UWB antenna. First, radiation is generated from diffractions at the rod end. By controlling the materials and geometry at the end of the rod, different radiation, gain, pattern, and bandwidth can be achieved. A high-gain “polyrod” antenna was developed by using a long, tapered leaky-wave section at the end with a reported bandwidth of up to 2:1. A greater bandwidth can be achieved by adding multiple higher dielectric layers inside the rod to avoid pattern narrowing and higher waveguide modes. Recently, a double-layer, dual-polarization UWB dielectric rod probe antenna design was developed as a near-field probe with a bandwidth of more than 4:1. Several desirable features for a good near-field probe include²¹ (1) low radar cross section (RCS) area, desired to minimize the mutual coupling between a probe and the antenna under test (AUT); (2) dual-linear polarization with good polarization isolation; and (3) a broad beamwidth with a stable radiation phase center. These features are important to reduce probe correction error^{22,23} and to improve the accuracy of near-field to far-field transformation.

UWB DRP Configurations

A double-layer UWB dielectric rod probe antenna design that has a bandwidth of greater than 4:1 is illustrated in Figure 19-8. It consists of feeding, guiding, and radiating sections. A resistively terminated TEM launcher launches broadband electromagnetic waves into a guiding section where TEM waves are converted into HE_{11} mode. Finally, a specially designed radiation section produces stable and symmetric radiation patterns with a radiation center located near the tip. The final antenna is enclosed in a cylindrical conducting cylinder containing some absorbers to eliminate undesired radiations from feed and launchers. An absorber sleeve is placed around the exposed section of the rod with a 0.25-in air gap between rod and absorbers. Such an enclosure arrangement is to ensure that radiations only come from the radiation section.

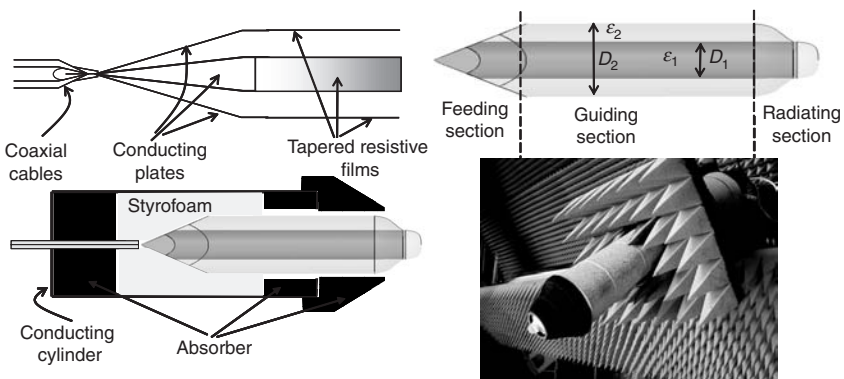

FIGURE 19-8 UWB dual-polarization dielectric rod probe antenna with more than 4:1 bandwidth and symmetric radiation patterns

FIGURE 19-9 The feed section of a single-layer rod (2-in diameter) antenna with dual-polarization launchers (the scale on the ruler is inches)

Feed Section

The feed section shown in Figure 19-9 is responsible for launching UWB electromagnetic waves into the rod. This is achieved by a Type-II UWB launcher that consists of a pair of resistively terminated conducting plates that are mounted on the opposite surfaces of the feed section whose diameter is gradually increased to avoid excitation of higher mode. The geometry of the conducting plates is chosen to provide a desirable surge impedance of $100\ \Omega$, matched to the output impedance of the balun. The input impedance of the balun is $50\ \Omega$. The resistive tapering profile is plotted in Figure 19-9. The launcher design dictates the low-frequency limit of the rod antenna since little energy will be guided by the rod when the guided wavelength becomes much greater than the diameter of the rod. By adding a second launcher on the orthogonal plane, dual polarization can be easily achieved.

Guiding Section

The diameter and the dielectric constant (the outer layer, inner core) are chosen to be 2 inches and 1 inch, and $\epsilon_1 = 4$ and $\epsilon_2 = 6$, respectively. Figure 19-10 compares the calculated magnitude of electric fields guided by a single-layer (left) and double-layer (right) rod along the longitudinal cut at 2, 4, and 8 GHz. Both rods are 2-in diameter. The single-layer rod is lossless and has a dielectric constant of 4. The double-layer rod is also lossless and has dielectric constants of 4 and 6 in the outer layer and inner core (1-in diameter), respectively. In both cases, HE_{11} mode fields are excited from the bottom ends. For the single-layer rod, the amount of energy guided within the rod increases with frequency as expected. However, once most fields are guided within the rod, further frequency increase does not further reduce the size of the transverse field distribution. This can be seen at the top end of the single-layer rod at 8 GHz. If we let fields radiate from the top end, it will have a large effective radiation aperture (in terms of wavelength) at high frequencies, causing undesired pattern narrowing and lobes. As a comparison, the fields guided by the double-layer rod are mainly confined to the higher dielectric inner core at high frequencies. This would reduce the effective aperture size (in terms of wavelength) at high frequency. Therefore, it is conjectured that if thickness and dielectric constant of each layer of a multiple-layer rod are chosen properly, the frequency scaled radiation aperture should be obtainable and produce UWB gain and patterns.

Radiating Section

Figure 19-11 shows the geometry of the radiating section of the UWB rod antenna. Radiation arises from refraction and diffraction caused by the gradually reduced diameter.

FIGURE 19-10 Comparison of field distribution (in the center longitudinal plane) of waves guided by single and double dielectric rods

We can also taper the dielectric constant down to produce radiations.²⁴ As the guided wave approaches the radiating section whose electrical size becomes much smaller than the guided wavelength, the fields can no longer be confined to the rod, causing radiation as illustrated in Figure 19-11. The length of the radiation section should be kept short

FIGURE 19-11 The radiating section of the UWB double-layer dielectric rod antenna

FIGURE 19-12 Measured VSWR (left) and return loss in time domain (right)

to avoid dispersion and pattern narrowing since shorter wavelengths can still be guided longer and radiate out near the top. However, a shorter length makes designing a smooth tapering more challenging. Internal reflections should also be minimized by a smooth tapering. Since the inner core has a higher dielectric constant, a small low-dielectric cover ($\epsilon_r = 2.2$) is added to provide a better transition into the air, thus reducing internal reflections at high frequencies.

Antenna Characteristics

Figure 19-12 plots the measured VSWR and time-domain return loss. The VSWR is < 2 within the 2~8-GHz band. The oscillatory behavior is caused by the interference between feed and tip reflections as clearly observed at the 7-ns and 10-ns position. The measured and simulated co- and cross-polarization gain in the boresight direction are plotted in Figure 19-13 (upper left), which shows a stable gain level of 2~5 dBi. The cross-polarization component appears to be approximately 20 dB below the copolarization component over the entire frequency range. The simulated and measured radiation patterns at 2, 4, and 8 GHz are also plotted in Figure 19-13. The designed goal of 60° beamwidth as a near-field probe is clearly met. The patterns also are relatively symmetrical in the E - and H -planes in the main beam region.

19.7 THE DUAL-POLARIZATION UWB DIELECTRIC HORN ANTENNA DESIGN

Introduction

A UWB dielectric horn antenna (DHA) was developed²⁵ for operating from 2 to 18 GHz. This is a Type-II UWB antenna because it utilizes absorbing materials to control undesired lateral waves and curved surface to reduce end diffraction such that there is only one source of radiation. The DHA's design objective is to provide dual-linear polarizations, wide and stable beamwidth, and symmetric radiation patterns. Figure 19-14 shows pictures of an assembled and partially assembled 2–18-GHz DHA antenna. The basic DHA configuration consists of a solid dielectric horn, a wave launcher, and a surrounding bulk absorber,

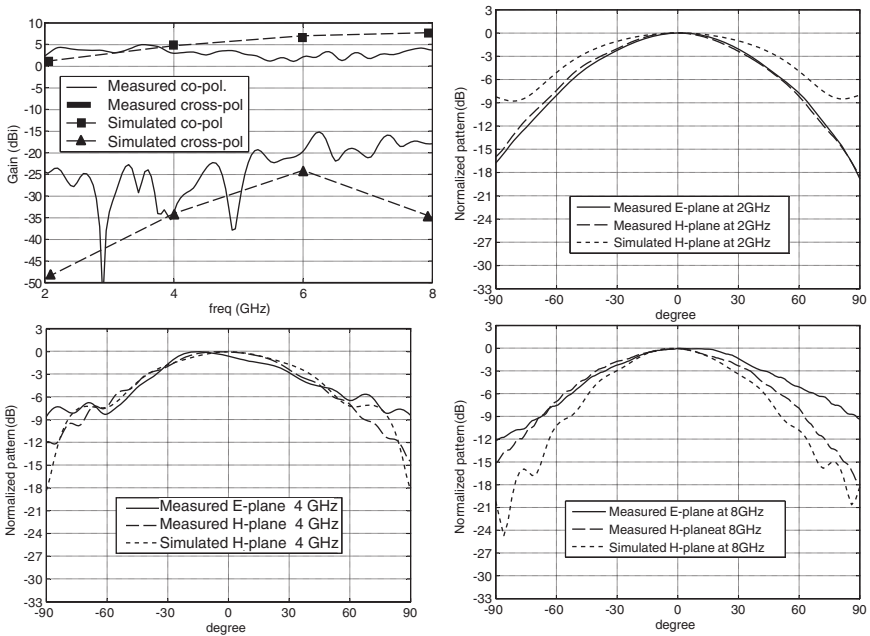

FIGURE 19-13 Measured and simulated realized gain and radiation patterns

as shown in Figure 19-14. Notice that this is not a dielectric loaded antenna. The dielectric horn is the primary radiator. This DHA design offers a much broader bandwidth (9:1) compared with most other dielectric horn antenna designs.²⁶

Wave Launchers and Feeding Arrangement

Similar to the previous dielectric rod antenna, each launcher arm begins with a triangular conducting plate and is followed by a tapered resistive strip. The surge impedance is a function of plate angle, horn angle, and the dielectric constant²⁷ and is chosen to be approximately

FIGURE 19-14 Basic configuration for the UWB DHA design

FIGURE 19-15 Balun and feeding cable arrangement of DHA design

100 Ω , matched to the output impedance of a balun that has 50- Ω input impedance (see Figure 19-15). The minimum length of the conducting plate is related to the antenna's low-frequency limit of antenna gain. The maximum length of the plate is related to the high-frequency limit of the radiation pattern.

The resistance profile of the resistively tapered strip is similar to the one shown in Figure 19-9 and is used to reduce launcher resonance. If the resistance value increases too rapidly, undesirable diffractions could occur along the tapering. On the other hand, if the resistance value increases too slowly, undesired reflections could occur at the end of the tapering due to short length. The width and length of the resistive film should be kept minimal to maintain dielectric-air boundary condition and to avoid the excitation of the cross-polarized fields. Of course, the utilization of such resistive loading is at the expense of lower radiation efficiency.

Surrounding Absorber

The surrounding absorber is used to suppress undesired lateral waves propagating along the sides. Such lateral waves exist when there is an interface between two media with different dielectric constants.²⁸ Figure 19-16 plots calculated field distribution of an

FIGURE 19-16 Propagation of impulse fields in DHA

impulse signal in a dielectric wedge with a dielectric constant of 9 and wedge angle of 60° . Without the external absorber (left figure), strong lateral waves are excited. Such lateral waves are easily identified by the angle, $\sin^{-1}(\epsilon_{\text{external}}/\epsilon_{\text{internal}})$, their wavefronts made with the dielectric interface. The presence of these lateral waves eventually will also interfere with radiation from the space wave, causing undesired variation in the gain and pattern with frequency and angle.²⁹ Since lateral waves extend to the external medium, they can be suppressed by applying an external absorber. It is evident that lateral waves have been largely suppressed with only little impact on space waves. Also notice the much weaker external fields, which are beneficial in suppressing side and back lobes.

Dielectric Horn

The end of the dielectric horn has a spherical surface with its spherical center being at the feedpoint. A low-loss dielectric material, polymethyl-methacrylate (acrylic), is chosen for its low cost and easy fabrication. Acrylic also has good ultraviolet (UV) and thermal stability, low water absorption, and high dielectric strength. Its typical refractive index is approximately 1.48 over the frequency range of interest (2–18 GHz). Although choosing a material with a higher dielectric constant could reduce external waves and reduce antenna dimensions, it also increases undesired internal reflection at the spherical aperture and diffractions at edges. Such reflections could be reduced via the utilization of proper dielectric tapering along the radial direction for a smooth impedance transition.

The horn angle should be chosen based on desired beamwidths. Our empirical data showed the -10 -dB beamwidth was approximately 10° – 13° less than the horn angle (less than 70°). A larger horn angle produces a wider beamwidth but requires wider launcher arms to maintain the same input impedance. This may be problematic since it can increase the cross coupling in a dual-polarization design. A large horn angle is also more susceptible to higher-order modes that could be excited by slight asymmetry in the two launcher arms. Figure 19-17 plots snapshots of computed pulsed fields in a DHA with a horn angle of 130° and dielectric constant of 2.2. This simulation adopts a realistic absorber with a dielectric constant of 1.8 and conductivity of 0.22 S/m at 10 GHz. It is observed that the fields propagate outward spherically without experiencing magnitude and phase distortion. The fields are also confined within the horn. To further reduce undesired diffractions at the edge of the spherical end, an improved design adopts smoothly curved sides, as illustrated in Figure 19-18. Notice the pyramidal geometry near the feed region for achieving improved isolation between

FIGURE 19-17 Propagation of pulsed fields in a dielectric horn

FIGURE 19-18 Dielectric horn geometry of improved DHA design for reducing edge diffraction

orthogonal polarizations in a dual-polarization design compared with the circular cone geometry (see Figure 19-14).

Antenna Characteristics

In this section, measured data for a DHA designed for 2–18-GHz dual-polarization operations with a beamwidth of approximately 60° are presented. This DHA is pictured in Figure 19-14. The radius and angle of the horn are 3.5 in and 110°, respectively. Figure 19-19 shows the measured VSWR, which is less than 1.5 for most of the band and below 2.0 over

FIGURE 19-19 Measured VSWR from 2 to 18 GHz

the entire band. Although this is somewhat expected due to the utilization of resistively loaded launchers, this result does indicate low reflection from spherical aperture, the main reason for not using high-dielectric material. The antenna efficiency of this DHA is around 10 percent and 27 percent at 2 GHz and 18 GHz, respectively. The solid and dashed lines are used to distinguish the two orthogonal polarizations.

Figure 19-20 plots measured boresight gain (co- and cross-polarization components) for two orthogonal polarizations. The gain level increases approximately 5 dB from 2 to 18 GHz. The small rapid fluctuations are clutter from the measurement facility. The low gain level is due to the utilization of the absorber and the tapered resistive strips. Unfortunately, the absorber is necessary in the current design to eliminate the lateral waves. However, a high gain antenna is not a critical need in many applications as in the indoor ranges. To adapt the antenna to other applications where a higher gain level is desired, other launcher designs that could avoid launching lateral waves are possible and are being investigated. The copolarization-to-cross-polarization isolation decreases monotonically from 25 dB at 2 GHz to 15 dB at 18 GHz. This behavior of decreasing isolation is caused by slight misalignments in placing the launcher arms or feeding wires.

Figure 19-21 plots the normalized measured far-field patterns, which also agree well with simulated data²⁵ (not shown here). These patterns show good *E*- and *H*-plane symmetry as well as stable beamwidth. It is observed that the beamwidth below 4 GHz becomes significantly wider since the cross sectional size at the effective end of the launcher is small compared with wavelength such that HE_{11} mode is only loosely guided. Thus, for our application, the antenna has a 9:1 bandwidth. Only the radiation patterns for one of the two orthogonal polarizations are shown here since both polarizations have similar patterns.

20.1 INTRODUCTION

In this chapter, the theoretical and practical consideration involved in the design of phased array antennas is given. The intent is to provide the antenna designer with an overview of the basic design concepts of phased arrays and the means to determine the proper antenna parameters for a given application. This chapter is an updating of that prepared for the previous edition by Ray Tang and Richard Burns. They were associated with Hughes Aircraft Co., Fullerton, California.

Basic Concept of Phased Arrays

Basically, the phased array antenna is composed of groups of individual radiators (elements), which are distributed and oriented in a linear or two-dimensional spatial configuration. The amplitude and phase excitations of each element can be individually controlled to form a radiated beam of any desired shape (from a directive pencil beam to a fan beam shape) in space. The position of the beam in space is controlled electronically by adjusting the phase of the excitation signals at the individual elements. Hence, beam scanning is accomplished with the antenna aperture remaining fixed in space without the involvement of mechanical motion in the scanning process. In other words, this is scanning without inertia.

Advantages of Phased Arrays

The capability of rapid and accurate beam scanning in microseconds permits the system to perform multiple functions, either interlaced in time or simultaneously. An electronically-steered array radar is able to track a large number of targets and illuminate some of these targets with radio frequency (RF) energy, for the purpose of guiding missiles toward them. This form of radar can perform complete hemispherical searches, with automatic target selection and hand-over to tracking. It may even act as a communication system, directing high gain beams toward distant receivers and transmitters. Complete flexibility is possible. Search and track rates may be adjusted to best meet the particular situation within the limitations set by the total use of time. The antenna beamwidth may be changed electronically, by means of phase spoiling, to cover certain areas more rapidly but with less gain. Very high powers may be generated from a multiplicity of generators distributed across the aperture. Electronically controlled phased-array antennas can give the flexibility needed to perform all the various functions in a way best suited to the specific task at hand. The functions can be programmed rapidly and accurately with digital beam steering computers.

Overview of the Chapter

The first part of this chapter describes the theory of phased-array antennas, with emphasis on the basic relationships between the array performance, the excitation coefficients (amplitude and phase) of each element, and the physical parameters of the antenna (see Sections 20.2 and 20.3). These relationships are the design formulas, which an antenna designer can use to determine the required array parameters that satisfy a given set of system requirements. After determining the array parameters such as the number of required elements, the spacing between the elements, and the size of the radiating aperture, the next step in the design would be the selection of the type of element, phaser, and beamforming

feed network to implement the required excitations at the radiating aperture physically. A detailed discussion of the various types of elements and feed networks that are commonly used is given in Sections 20.4 and 20.5, respectively. Corresponding to the various types of feed networks, the frequency-bandwidth characteristics of the phased-array antenna are described in Section 20.5.

20.2 THEORY OF PHASED ARRAYS

We shall begin the discussion of array theory with the simplest configuration possible: an array of isotropic elements equally spaced along a line (linear in a geometric sense). It will be seen that the more complex array theory can be framed as an extension of this simple case. For example, two-dimensional arrays are often constructed of interconnected linear arrays. From the linear array discussion, we will then proceed to the theory of two-dimensional arrays. The theory of arrays of isotropic radiators will then be extended and modified to apply to arrays of real elements.

To simplify and condense the material to be presented, the following assumptions will be adhered to in this discussion:

1. For practical purposes the far-field region of the antenna, commonly defined by ranges R , satisfying

$$R \geq \frac{2L^2}{\lambda} \quad (20-1)$$

where L is the largest dimension of the antenna and λ is the operating wavelength of interest. In this region, the antenna pattern is insensitive to range except for a scale factor of $1/R^2$ in power. This scale factor is usually ignored.

2. The reciprocity theorem¹ will be used extensively to justify analysis of array far-fields from either the transmitting or the receiving viewpoint, as convenience dictates and usually without explicit mention. By virtue of this theorem, the pattern will be the same in either case if no nonreciprocal devices are used. When such devices are used, one can usually perform pattern analyses which neglect their presence.
3. For simplicity, interest will be restricted to the responses of arrays to continuous wave (CW) signals.

Radiation Pattern of Linear Arrays

The theory of linear arrays is described in detail by Silver¹ and Schelkunoff.² Let us consider the elementary array of Figure 20-1, consisting of N isotropic elements, equally spaced at a distance d apart. On receive, if a plane wave is incident upon the array from a direction making an angle θ with the array normal, the current in the n th element will be of the form

$$i'_n = A e^{jnk d \sin \theta} \quad (20-2)$$

where A is a complex constant related to the instantaneous amplitude and phase of the plane wave and k is the wave number:

$$k = \frac{2\pi f}{c} = \frac{2\pi}{\lambda} \quad (20-3)$$

FIGURE 20-1 Basic linear array configuration

where

f = operating frequency

c = velocity of light

Eq. 20-1 shows that the current in the n th element leads that in the $(n + 1)$ th element by a phase shift given by $\Delta\psi = kd \sin \theta$. This phase shift corresponds to the difference in time of arrival τ of the plane wavefront of $\tau = d/c \sin \theta$. If we place a control element behind each radiator, as indicated in Figure 20-2, with a transfer coefficient for the n th element given by

$$\frac{i''_n}{i'_n} = a_n e^{j\psi_n} \quad (20-4)$$

where a_n and ψ_n are the *real* current gain and phase shift of the control element, respectively, the summing network produces an output

$$E_a(q) = \sum_{n=0}^{N-1} a_n e^{j(\psi_n + nkd \sin \theta)} \quad (20-5)$$

where we now neglect the constant A of Eq. 20-2. This relationship gives the response of the array of Figure 20-2 to a signal arriving from a direction θ in terms of the set a_n 's and ψ_n 's. The set of coefficient a_n is usually called the *array amplitude taper*, while the ψ_n 's are called the *phase taper*. The expression of Eq. 20-5 is called the *array factor*. To combine the received signals from all the radiators in phase to produce a maximum response in the scan direction of θ_0 , the ψ_n 's must have the form

$$\psi_n = -nkd \sin \theta_0 \quad (20-6)$$

This expression shows that the required phase taper across the array aperture is a linear taper (constant phase differential between adjacent radiators). On transmit, when the phases

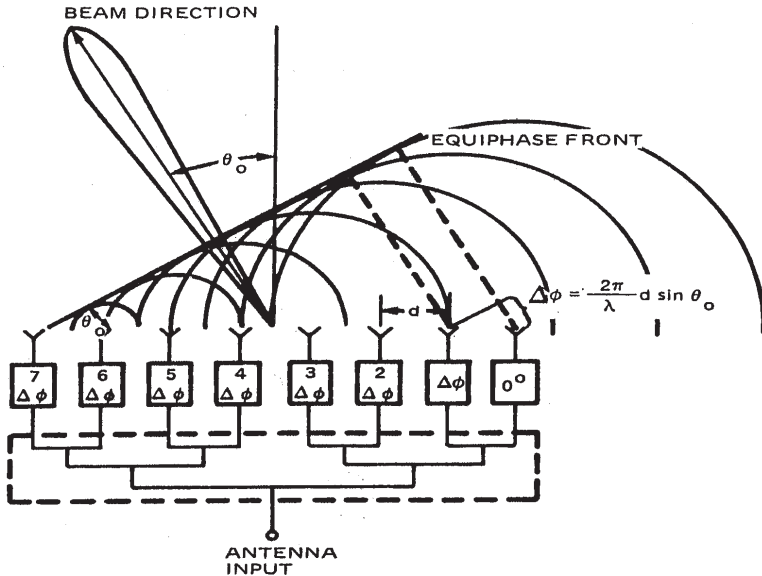

FIGURE 20-2 Beam-steering concept using phasers (phase shifters) at each radiating element

of the control elements such as phasers are set to the phase taper of Eq. 20-6, the signals radiated from all the elements will add up in phase to produce a main beam in the direction of θ_0 . Hence, the array factor of Eq. 20-5 is the same for both transmit and receive. Substituting Eq. 20-6 into Eq. 20-5, we have for the array factor

$$E_a(\theta) = \sum_{n=0}^{N-1} a_n e^{jnk d (\sin \theta - \sin \theta_0)} \quad (20-7)$$

For the special case of a uniformly illuminated array, $a_n = 1$ for all n , the array factor for an N -element array becomes

$$E_a(\theta) = \frac{\sin \left[N\pi \frac{d}{\lambda} (\sin \theta - \sin \theta_0) \right]}{N \sin \left[\pi \frac{d}{\lambda} (\sin \theta - \sin \theta_0) \right]} \quad (20-8)$$

Grating Lobes Versus Element Spacing

The array factor of Eq. 20-7 can also be expressed in terms of the variable $v = \sin \theta$ as follows:

$$E_a(v) = \sum_{n=0}^{N-1} a_n e^{jnk d (v - v_0)} \quad (20-9)$$

where the beam direction v_0 is related to the differential phase $\Delta\psi$ by $\Delta\psi = -kdv_0$. It is obvious that $E_a(v_0)$ and $E_a(\theta)$ are related by a one-to-one mapping in the region $|v| \leq 1$, which is often referred to as the *visible space* corresponding to the real angles of θ . It is also apparent that $E_a(v)$ is a periodic function of v of period

$$\frac{2\pi}{kd} = \frac{1}{d/\lambda} = \frac{\lambda}{d} \quad (20-10)$$

and that Eq. 20-9 is in the form of a Fourier series representation, which is readily analyzable and easy to visualize. The maxima of $E_a(v)$ occur whenever the argument of Eq. 20-9 is a multiple of 2π , for example, $kd(v - v_0) = 2i\pi$, where $i = 0, \pm 1, \pm 2, \dots$, or

$$v_i - v_0 = \frac{i}{d/\lambda} \quad (20-11)$$

When $v_i = v_0$ or $i = 0$, this maximum is generally referred to as the *principal lobe* (PL) or main beam, and the other maxima are known as the *grating lobes* (GL) from the corresponding phenomena with optical gratings. In the design of phased arrays, it is imperative that the grating lobes be eliminated within the visible space since these lobes reduce the power in the main beam and thus reduce the antenna gain, and introduce unwanted signals and noise. This means that the element spacing d must be chosen to avoid the grating lobes over the range of v from -1 to $+1$. When the main beam is scanned to v_0 , the closest grating lobe to the visible space is located at $v_i = v_0 - \lambda/d$ (see Figure 20-3). This grating lobe will just appear in visible space (at the endfire direction of the array) when $v_0 - \lambda/d = -1$, or

$$\frac{d}{\lambda} = \frac{1}{1 + \sin |\theta_0|} \quad (20-12)$$

Thus, the element spacing criterion stated in terms of the desired maximum scan angle $\theta_{0\max}$ is

$$\frac{d}{\lambda} < \frac{1}{1 + \sin |\theta_{0\max}|} \quad (20-13)$$

FIGURE 20-3 Grating-lobe formation

FIGURE 20-4 Scan angle versus element spacing for GL appearance

Figure 20-4 is a plot of Eq. 20-13. Note that GL appear when element spacing is sufficient; scan only moves the GL. For small arrays, the grating lobe null may be positioned at 90° :

$$\frac{d}{\lambda} = \frac{N - \sqrt{1 + \beta^2}}{N(1 + \sin \theta)} \quad (20-14)$$

where $\beta = 0$ for uniform excitation, or B for Taylor One-Parameter distribution. The analysis of Eq. 20-14 is due to David Munger and Richard Phelan.

Sub-Arrays and Quantization Lobes

Linear or planar arrays for limited scan may employ sub-arrays, where a small group of elements (sub-arrays) are fed together. Thus expensive hardware such as phasers, preamps, power amps, and combiners is minimized. When scanned, an array of contiguous sub-arrays has a stair-step phase, with one step over each sub-array. This gives rise to *quantization lobes* (QL). These are located at approximately the grating lobe angles, except that the sub-array width W is used in Eq. 20-11. QL amplitudes are given approximately by $\text{sinc}(\pi W/\lambda \sin \theta)$. For example, for $W/\lambda \sin \theta = .3$ the QL amplitude is -12.6 dB, while for $W/\lambda \sin \theta = .5$ the QL is -3.9 dB. Note that unlike GL, which appear whenever element spacing is adequate, QL appear only when the beam is scanned away from broadside.³

FIGURE 20-5 100 element array, 2 element subarray, and 30° scan

Quantization lobes can be significantly attenuated by clever use of random numbers, as shown by Smith and Guo.⁴ Random numbers are added to the drive of the digital phasers; then the same set, truncated to the number of phaser bits used, is subtracted. If the random numbers are chosen properly, the QL are depressed. Figure 20-5 shows an array pattern with two element sub-arrays at 30° scan. When the pseudo-randomization technique is used, the QL are reduced.⁵

Radiation Pattern of Planar Arrays

To provide beam scanning in two angular dimensions, a planar array of radiating elements must be used. In a spherical coordinate system, the beam position is defined by the two coordinates θ and ϕ , as shown in Figure 20-6. Also shown in Figure 20-6 is the layout of the element lattice in the planar array. For a rectangular lattice, the mn th element is located at $x_m = md_x$ and $y_n = nd_y$. For a triangular lattice, the element grid can be thought of as a rectangular grid in which every other element has been omitted. In this case, only every other value of mn contains an element. The element locations can be defined by requiring that the $(m + n)$ be even.

The array factor of a two-dimensional array may be calculated by summing the vector contribution of each element in the array at each point in space. The array factor can be written in terms of the directional cosines, $\cos \alpha_x$ and $\cos \alpha_y$, of the spherical coordinate system as follows:

$$E_a(\cos \alpha_x, \cos \alpha_y) = \sum_m \sum_n i_{mn} e^{jk(md_x \cos \alpha_x + nd_y \cos \alpha_y)} \quad (20-15)$$

FIGURE 20-6 Element geometry of a two-dimensional array

where

$$\begin{aligned}\cos \alpha_x &= \sin \theta \cos \phi \\ \cos \alpha_y &= \sin \theta \sin \phi\end{aligned}\quad (20-16)$$

For a uniformly illuminated ($i_{mn} = 1$) rectangular array, we have

$$E_a(\cos \alpha_x, \cos \alpha_y) = \sum_{m=-(M-1)/2}^{(M-1)/2} e^{jkmd_x \cos \alpha_x} \sum_{n=-(N-1)/2}^{(N-1)/2} e^{jkn d_y \cos \alpha_y} \quad (20-17)$$

Each sum can be evaluated, producing a result analogous to Eq. 20-8 for a uniformly illuminated linear array:

$$E_a(\cos \alpha_x, \cos \alpha_y) = \left[\frac{\sin \left(\pi M \frac{d_x}{\lambda} \cos \alpha_x \right)}{M \sin \left(\pi \frac{d_x}{\lambda} \cos \alpha_x \right)} \right] \left[\frac{\sin \left(\pi N \frac{d_y}{\lambda} \cos \alpha_y \right)}{N \sin \left(\pi \frac{d_y}{\lambda} \cos \alpha_y \right)} \right] \quad (20-18)$$

Beam scanning with planar arrays is accomplished by linear phasing along both array coordinates. To scan the beam to the angular position corresponding to the directional cosines $\cos \alpha_{x0}$ and $\cos \alpha_{y0}$, a linear phase taper is introduced at each element so that the excitation at the mn th element is given by

$$i_{mn} = a_{mn} e^{j(kmd_x \cos \alpha_{x0} + kn d_y \cos \alpha_{y0})} \quad (20-19)$$

where

$kd_x \cos \alpha_{x0}$ = element-to-element phase shift in the x direction

$kd_y \cos \alpha_{y0}$ = element-to-element phase shift in the y direction

This form of steering phase indicates that the phase of the m th element is the sum of a row phase $mkd_x \cos \alpha_{x0}$ and a column phase $nkdy \cos \alpha_{y0}$.

The array factor of a rectangular planar array of M by N elements is then given by

$$E_a(\cos \alpha_x, \cos \alpha_y) = \sum_m \sum_n a_{mn} e^{jk[md_x(\cos \alpha_x - \cos \alpha_{x0}) + nd_y(\cos \alpha_y - \cos \alpha_{y0})]} \quad (20-20)$$

Element Spacing and Lattice of Planar Arrays

As in the case of the linear array, the array factor of the planar array Eq. 20-18 has an infinite number of grating lobes in the directional cosine space. For example, the maxima of E_a occurs whenever the argument of Eq. 20-18 is a multiple of 2π . Since there is a one-to-one correspondence between the directional cosine space ($\cos \alpha_x$ and $\cos \alpha_y$ space) and the visible space (θ and ϕ space within the boundary defined by $\cos^2 \alpha_x + \cos^2 \alpha_y = 1$), the number of grating lobes that can be projected from the directional cosine space into the visible space depends upon the parameters d_x/λ and d_y/λ . To avoid the formation of grating lobes in the visible space, the element spacings d_x/λ and d_y/λ must be chosen so that there is only one maximum from Eq. 20-18, namely, the main beam, in the visible space (real space). In the planar array, the element lattice and spacing can be chosen to shape the grating lobe contour (location pattern of grating lobes) to fit the required scanning volume, so that the total required number of elements in the planar array is minimized. To accomplish this optimization, it is more convenient to plot the position of the grating lobes when the main beam is phased for broadside and observe the motion of these lobes as the beam is scanned. Figure 20-7 shows the grating lobe locations for both rectangular and triangular spacings. For a rectangular lattice, the grating lobes are located at

$$\begin{aligned} \cos \alpha_x - \cos \alpha_{x0} &= \pm \frac{\lambda}{d_x} \cdot p \\ p, q &= 0, 1, 2, \dots \\ \cos \alpha_y - \cos \alpha_{y0} &= \pm \frac{\lambda}{d_y} \cdot q \end{aligned} \quad (20-21)$$

FIGURE 20-7 Grating-lobe locations for rectangular and triangular element lattices

FIGURE 20-8 Construction of array factor $E(\phi, \theta)$ by projection of array function $E(\tau, \mu)$ onto unit sphere

The grating lobe pattern of Figure 20-7 must be mapped onto the surface of the unit sphere, as shown in Figure 20-8, to give a true spatial distribution; therefore, only the portion of the pattern of Figure 20-7 inside a unit circle centered at $\cos \alpha_x = \cos \alpha_y = 0$ lies in visible space. The lobe at $p = q = 0$ is the main beam. For a conical scan volume, the triangular grid is more efficient for the suppression of grating lobes than a rectangular grid,⁶ so that for a given aperture size fewer elements are required. If the triangular lattice contains elements at md_x and nd_y , where $m + n$ is even, then the grating lobes are located at

$$\cos \alpha_x - \cos \alpha_{x0} = \pm \frac{\lambda}{2d_x} \cdot p$$

$$p, q = 0, 1, 2, \dots \quad (20-22)$$

$$\cos \alpha_y - \cos \alpha_{y0} = \pm \frac{\lambda}{2d_y} \cdot q$$

where $p + q$ is even.

As the array is scanned away from broadside, each grating lobe (in directional cosine space) will move a distance equal to the sine of the angle of scan and in a direction determined by the plane of scan. To ensure that no grating lobes enter visible space (real space), the element spacing must be chosen so that for the maximum scan angle θ_m the movement of a grating lobe by $\sin \theta_m$ does not bring the grating lobe into visible space. If a scan angle

of 60° from broadside is required for every plane of scan, no grating lobe may exist within a circle of radius $1 + \sin \theta_m = 1.866$. The square lattice that meets this requirement has

$$\frac{\lambda}{d_x} = \frac{\lambda}{d_y} = 1.866 \quad \text{or} \quad d_x = d_y = 0.536\lambda \quad (20-23)$$

Here, the area per element is

$$dx \cdot dy = (0.536\lambda)^2 = 0.287\lambda^2 \quad (20-24)$$

For an equilateral triangular lattice, the requirement is satisfied by

$$\frac{\lambda}{d_y} = \frac{\lambda}{\sqrt{3}d_x} = 1.866 \quad \text{or} \quad d_y = 0.536\lambda, d_x = 0.309\lambda \quad (20-25)$$

If we recall that elements are located only at every other value of mn , the area per element is

$$2d_x d_y = 2(0.536\lambda)(0.309\lambda) = 0.322\lambda^2 \quad (20-26)$$

For the same amount of grating lobe suppression, the saving in the number of elements for the triangular versus the rectangular lattice is 15.5 percent. The grating lobe contour plots illustrating the previous example are shown in Figure 20-9.

Directivity of Linear Arrays

Array directivity is defined as the ratio of power density per unit of solid angle at the peak of the main beam to the average power radiated per unit solid angle over all space.

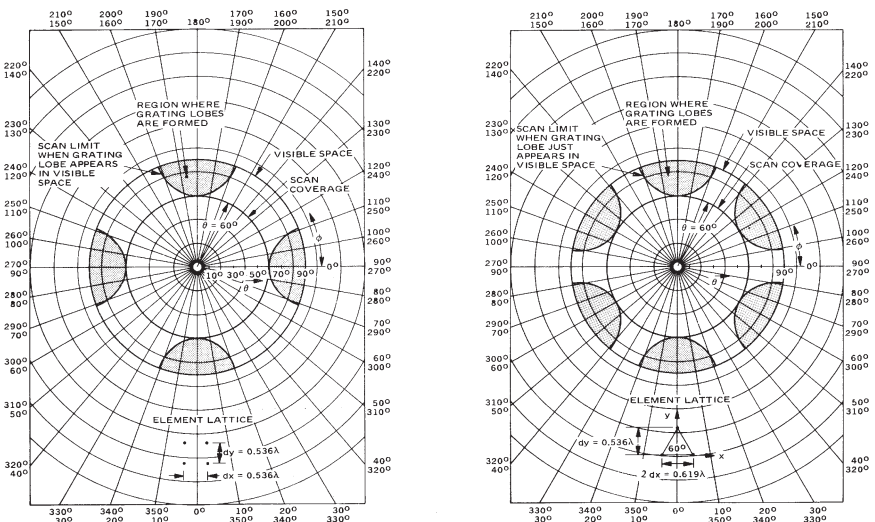

FIGURE 20-9 Grating lobe contours for rectangular and triangular lattices

From this definition, it follows that the directivity of the main beam at angle θ_0 is given by

$$D(\theta_0) = \frac{|E(\theta_0)|^2}{\frac{1}{4\pi} \int_{\text{all space}} |E(\theta_0)|^2 d\Omega} \quad (20-27)$$

where $d\Omega = \cos \theta d\theta d\phi$. For a linear array of isotropic radiators arranged as shown in Figure 20-10, $E(\theta)$ is independent of ϕ . Therefore, $\int |E|^2 d\Omega = 2\pi \int |E|^2 \cos \theta d\theta$. Using $v = \sin \theta dv = \cos \theta d\theta$, we have

$$D(v_0) = \frac{2 |E(v_0)|^2}{\int_{-1}^{+1} |E(v)|^2 dv} \quad (20-28)$$

Using Eq. 20-8 and integrating yield

$$D(v_0) = \frac{\left| \sum_{n=0}^{N-1} a_n \right|^2}{\sum_{n=0}^{N-1} \sum_{m=0}^{N-1} a_m a_n \frac{\sin 2\pi(d/\lambda)(n-m)}{2\pi(d/\lambda)(n-m)}} \quad (20-29)$$

FIGURE 20-10 N-element linear array geometry

The denominator of Eq. 20-29 prevents a simple analysis of the directivity. When all excitation coefficients are equal, the directivity simplifies to

$$D(v_0) = \frac{N^2}{N + 2 \sum_{n=1}^{N-1} \frac{(N-n) \sin 2nkd}{2nkd}} \quad (20-30)$$

This result is plotted in Figure 20-11 for arrays of 2 to 24 elements, with spacings up to 1.2λ . It may be noted that the directivity drops abruptly at the appearance of the first grating lobe.

FIGURE 20-11 Directivity of linear array of isotropes (after Hansen³ © Wiley 1998)

Directivity of Planar Arrays

The directivity of a planar array is defined as in Eq. 20-31 with appropriate notation changes to include both spatial angles:

$$D(\theta_0, \phi_0) = \frac{|E_a(\theta_0, \phi_0)|^2}{\frac{1}{4\pi} \int_{\text{all space}} |E_a(\theta, \phi)|^2 d\Omega} \quad (20-31)$$

where $d\Omega = d\theta d\phi \sin\theta$.

Even for an array of isotropic elements, equally excited, Eq. 20-31 is difficult to evaluate as the denominator contains the square of the array series. Directivity in terms of $\sin x/x$ functions of complicated arguments is given in Hansen.³ Fortunately, for scan angles not near endfire, the directivity is given approximately by

$$D(\theta_0, \phi_0) = \frac{4\pi A}{\lambda^2} \eta \cos\theta_0 \quad (20-32)$$

where η is the excitation or taper efficiency. Near endfire the beam shape and directivity change appreciably. For a large array

$$D(\theta_0, \phi_0) = 4\pi \eta N \frac{d_x d_y}{\lambda^2} \cos\theta_0 \quad (20-33)$$

The directivity expressions as shown in Eqs. 20-32 and 20-33 are for an array aperture which is impedance matched for all beam scan angles; for example, the aperture is transparent for a plane wave incidence at any scan angle θ_0 without reflections. However, in practice, the aperture is mismatched at some scan angles. Therefore, the array gain of the antenna is given approximately by

$$G(\theta_0, \phi_0) = \frac{4\pi A}{\lambda^2} \eta \cos\theta_0 [1 - |\Gamma(\theta_0, \phi_0)|^2] \quad (20-34)$$

where $|\Gamma(\theta_0, \phi_0)|$ is the amplitude of the array aperture reflection coefficient at the scan angle θ_0, ϕ_0 .

In general, the antenna beamforming network behind the array aperture has ohmic losses, such as the losses in the phasers, power combiners, etc.

To obtain an accurate gain formula, the effects of mutual impedance must be included. The resulting array gain versus scan angles is called Scan Element Pattern; see Section 20.4 for more details.

20.3 PATTERN CONTROL

Pattern Control of Linear Arrays

The far-field pattern properties of most frequent concern to the array designer are the array sidelobe level, array gain, and the beamwidth. All these properties depend upon the amplitude taper applied to the excitation coefficients a_n 's of Eq. 20-5. In general, a stronger amplitude taper across the array aperture has the effect of reducing the sidelobes at the expense of increased beamwidth and reduced aperture efficiency (antenna gain).

In the days before computers, aperture distributions were chosen for easy integrability: for example, cosine-on-a-pedestal. In the 1950s, Taylor at Hughes Aircraft developed aperture distributions based on physics principles. These principles required symmetric distributions, pedestals (so far-out sidelobes decayed as $1/u$), far-out zeroes separated by unity, and zeroes should be located on the w unit circle (Taylor^{3,7}). These widely used distributions include two for linear and rectilinear arrays, and two for circular arrays.

Taylor \bar{n} Distribution

The Taylor \bar{n} distribution⁷ provides a certain number of equal sidelobes, symmetrically located on both sides of the main beam with the amplitudes of the remaining sidelobes decreasing monotonically. For a given design sidelobe level, the Taylor distribution provides narrowest beamwidth. The Taylor \bar{n} amplitude distribution is of the form

$$A(x, A, \bar{n}) = \frac{1}{2\pi} \left\{ F(0, a, \bar{n}) + 2 \sum_{n=1}^{\bar{n}-1} F(n, A, \bar{n}) \cos \frac{n\pi x}{L} \right\} \quad (20-35)$$

$$F(n, A, \bar{n}) = \frac{[(n-1)!]^2 \prod_{m=1}^{\bar{n}-1} \left(1 - \frac{n^2}{\sigma^2 [A^2 + (-\frac{1}{2})^2]} \right)}{(\bar{n}-1+n)! (\bar{n}-1-n)!}$$

where

x = distance from center of aperture

L = total length of aperture

$A = 1/\pi \text{ arc cosh } R$

R = design sidelobe voltage ratio

$\sigma = \frac{\bar{n}}{\sqrt{A^2 + (\bar{n} + \frac{1}{2})^2}}$

\bar{n} = number of equiamplitude sidelobes adjacent to main beam on one side

Corresponding to this amplitude distribution, the beamwidth of a one-wavelength source is given by

$$\beta = \sigma \beta_0 \quad (20-36)$$

where

$$\beta_0 = \frac{2}{\pi} \sqrt{(\text{arc cosh } R)^2 - \left(\text{arc cosh } \frac{R}{\sqrt{2}} \right)^2} \quad (20-37)$$

For an array with aperture length L , the beamwidth is given by

$$\text{Beamwidth} = \sigma \beta_0 \frac{\lambda}{L} \text{ rad} \quad (20-38)$$

Beamwidth as a function of the design sidelobe level for various values of \bar{n} is given in Table 20-1.

TABLE 20-1 Design Sidelobe Level and Beamwidth for Taylor Distributions

Taylor One-Parameter Distribution

The modified $\sin \pi u/\pi u$ taper of the Taylor One-Parameter distribution³ produces monotonically decreasing sidelobes. The radiation pattern has a main lobe of adjustable amplitude and a sidelobe structure similar to that of the radiation from a uniformly illuminated source. The amplitude distribution is of the form

$$a(x) = I_0 \left[\pi \beta \sqrt{1 - \left(\frac{2x}{L} \right)^2} \right] \quad (20-39)$$

where

x = distance measured from center of aperture

L = total length of aperture

I_0 = zero order Bessel function of third kind

β = parameter fixing ratio R of main beam amplitude to amplitude of first sidelobe by
 $R = 4.60333 \sinh \pi \beta / \pi \beta$.

The array pattern corresponding to the previous amplitude distribution is given by

$$E_a(u) = \frac{\sin \pi \sqrt{u^2 - B^2}}{\pi \sqrt{u^2 - B^2}} \quad u \geq B \quad (20-40)$$

$$E_n(u) = \frac{\sinh \pi \sqrt{B^2 - u^2}}{\pi \sqrt{B^2 - u^2}} \quad u \leq B \quad (20-41)$$

where

$$u = (L/\lambda) \sin \theta \quad (20-42)$$

The beamwidth and aperture efficiency as a function of the design sidelobe ratio are shown in Table 20-2. Figure 20-12 shows a Taylor One-Parameter pattern for -25 dB sidelobe ratio. For details see Hansen.³

Dolph-Chebyshev Distribution

In 1946 Dolph⁸ showed that a linear aperture (array) would have maximum directivity for a given sidelobe level if all sidelobes were of equal height. This was accomplished by effecting

TABLE 20-2 Design Sidelobe Level, Beamwidth, and Aperture Efficiency for Modified $\sin \pi u/\pi u$ Distributions

a correspondence between the array polynomial and the Chebyshev polynomial. These distributions are mainly of academic interest for several reasons: the far-out sidelobes are high; for some cases the aperture distribution is non-monotonic; and the aperture efficiency is low.³

Bayliss Difference Pattern

For monopulse radar or angle-of-arrival systems, a difference pattern is useful. It typically has a split beam with zero gain at broadside. The steep slope of the pattern on either side of broadside allows accurate angle determination. The simplest arrangement uses a uniformly excited linear array with one half 180° out of phase with the other half. Unfortunately the highest sidelobe is -10.6 dB, a level often unacceptable. A remedy was provided by Bayliss,⁹ who developed a difference pattern based on the Taylor \bar{n} distribution discussed earlier. This allows lower difference pattern sidelobes to be selected versus excitation efficiency. Figure 20-13 shows a typical Bayliss pattern with -25 dB sidelobe level, while Figure 20-14 gives the amplitude distribution. Details of the equations and efficiencies are given in Hansen.³

Pattern Control of Planar Arrays

If markedly different patterns are desired in the two orthogonal planes ($\cos \alpha_x$ and $\cos \alpha_y$ planes), it is often advantageous to use rectangularly-shaped arrays with sides parallel to the specified planes and separable illumination; that is, $a_{mn} = a_m a_n$, so that

$$\begin{aligned} E_a(\cos \alpha_x, \cos \alpha_y) &= \sum_m \sum_n a_{mn} e^{jk[md_x(\cos \alpha_x - \cos \alpha_{x0}) + nd_y(\cos \alpha_y - \cos \alpha_{y0})]} \\ &= \sum_m a_m e^{jkmd_x(\cos \alpha_x - \cos \alpha_{x0})} \sum_n a_n e^{jknd_y(\cos \alpha_y - \cos \alpha_{y0})} \\ &= E_{a1}(\cos \alpha_x) \cdot E_{a2}(\cos \alpha_y) \end{aligned} \quad (20-43)$$

FIGURE 20-13 Bayliss difference pattern, $\bar{n} = 5$

where E_{a1} and E_{a2} are synthesized by linear array techniques. In this case, the amplitude distributions described in the subsection “Pattern Control of Linear Arrays” can be applied along each orthogonal axis of the planar array to achieve the desired sidelobe control. One special feature of this separable illumination is that the sidelobe levels in the $\cos \alpha_x$ plane are those of $E_{a1}(\cos \alpha_x)$ alone, since E_{a2} is a maximum. Away from both the $\cos \alpha_x$ and the $\cos \alpha_y$ axes (diagonal planes), the sidelobes are lower as a result of the product of E_{a1} and E_{a2} , both less than their maxima. For example, the array factor for a uniformly illuminated rectangular aperture was given by Eq. 20-18. The array factor yields first sidelobes of about -13.2 dB below the main beam along the two orthogonal axes. Off the axes, the sidelobes are lower. In particular, along the 45° diagonals, the first sidelobes are twice as low; -26.4 dB.

FIGURE 20-14 Bayliss difference pattern amplitude

Consequently, for a given peak sidelobe level, the taper efficiency ($\eta = \eta_1 \eta_2$) is lower for a separable illumination than that which can be realized by nonseparable means, although the average sidelobe level should be comparable to tapers of like values of η .

If a circularly symmetric pattern is desired, an array shape approximating a circle is preferred. Here, the array symmetry refers to only the symmetry of the beam shape and near-in-sidelobe structure. The element grid will still govern the grating lobe location. In most cases, the amplitude distributions for circular arrays are nonseparable.

Taylor Circular n -bar Distribution

This low sidelobe distribution^{10,11} produces a pattern that is rotationally symmetric. Design principles are similar to those of the linear \bar{n} distribution.³ Useful data are given in Table 20-3.

Hansen Circular One-Parameter Distribution

This symmetric distribution¹² uses a modified $I_1(\pi u)/\pi u$ in the higher part of the main beam, and a modified $J_1(\pi u)/\pi u$ for the rest of the main beam and sidelobes. The Bessel arguments are replaced by $\pi\sqrt{u^2 - H^2}$, where H corresponds to the B constant of the linear One-Parameter distribution. Table 20-4 gives design data.³

For the special case of a uniformly illuminated circular array, corresponding to $H = 0$ in the One-Parameter distribution, the array pattern is given by

$$E_a(\theta) \approx \frac{J_1(ka \sin \theta)}{ka \sin \theta} \quad (20-44)$$

where $J_1(x)$ is the first-order Bessel function. The function has an HPBW coefficient of 58.96° , defined by

$$\text{Beamwidth} = 58.96 \frac{\lambda}{2a} \quad (20-45)$$

where a is the radius of the circular aperture. The first sidelobes are approximately -17.5 dB.

There is also a circular Bayliss difference pattern. Details and references are given in Hansen.³

20.4 RADIATING ELEMENT DESIGN AND MUTUAL COUPLING

The discussion on array theory in Section 20.2 is based on elements with isotropic patterns. In practice, however, the radiation patterns of real elements are nonisotropic, and the impedance of the elements varies as a function of scan caused by the mutual coupling between the elements. In fact, the pattern of an element in the environment of an array is markedly different from the pattern of an isolated element in amplitude, phase, and, perhaps, polarization as well.

One of the functions performed by the antenna is to provide a good match between the radar transmitter and free space. This means that the driving point impedance looking into the element in the array environment must be matched to their generator impedance.

If the antenna aperture is not matched to free space, power will be reflected back toward the generator, resulting in a loss in radiated power. In addition, a mismatch produces standing waves on the feed line to the antenna. Therefore, while the antenna is radiating less power, individual components must be designed to handle more peak power. In a scanning array, the impedance of a radiating element varies as the array is scanned, and the matched problem is considerably more complicated. In some instances, spurious lobes may appear in the array pattern as a consequence of the mismatch. Furthermore, there are conditions in which an antenna that is well matched at broadside may have some angle of scan at which most of the power is reflected (scan blindness).

Design Criteria for Elements

The most commonly used elements for phased arrays are dipoles,¹³ waveguide slots,¹⁴ open-ended waveguides,¹⁵ TEM horns,^{16,17} spirals,¹³ and microstrip patch elements.¹⁸ The TEM horn is sometimes called the Vivaldi antenna, a whimsical name that has no content and is deprecated. The selection of an element for a particular application must be based upon the following considerations:

1. The required area of the element is small enough to fit within the allowable element spacing and lattice without the formation of grating lobes. In general, this limits the element to an area of a little more than $\lambda^2/4$.
2. The Scan Element Pattern of the element provides the appropriate aperture matching over the required scan coverage (see Section 20.4).
3. The polarization and power handling capability (both peak and average power) meet the system requirements.
4. The physical construction of the element must be able to withstand environmental requirements such as thermal, shock, and vibration requirements.
5. The element must also be inexpensive, reliable, and repeatable from unit to unit since many hundreds or thousands of elements are required in a large phased-array antenna.

Since the impedance and the pattern of an element in an array are determined predominantly by the array geometry and environment, the radiator may be chosen to best suit the feed system and the physical requirements of the antenna. For example, if the element is fed from a stripline or microstrip phaser, a stripline or microstrip patch would be a logical choice for that element.

After selecting the proper type of element on the basis of the criteria as stated previously, the next step is to optimize the performance by following the procedure outlined next:

1. Select an element configuration and spacing that do not generate grating lobes.
2. Formulate an analytical model of the radiating element in the array aperture, and optimize the performance by varying the design parameters of the element such as the spacing between the elements, the aperture size, or the distance of the element above ground. The Scan Impedance may be modeled by Floquet's infinite array theory, or by numerical methods such as the Moment Method, Finite Elements, or FDTD.
3. Using the analytical results from Step 2, fabricate waveguide simulators to measure the Scan Impedance at discrete scan. The design parameters of the element may have to be modified in order to optimize element performance. This measurement also verifies the calculated results of Step 2.
4. Fabricate a small test array and measure the Scan Element Pattern using the array in receive mode, over the required frequency band. The Scan Element Pattern describes the variation in array gain as a function of beam scan angle. Large aperture mismatches at any scan angle or scan plane will show up as dips in the Scan Element Pattern.
5. The Scan Element Pattern measurement of Step 4 in conjunction with the Scan Impedance measurement of Step 3 establishes the performance characteristics of the final element design.

Scan Element Pattern (SEP)

Scan Element Pattern, formerly called Active Element Pattern, is gain per element versus scan angles. *Active* is deprecated because it has electron device connotations. Mutual impedance effects are included. For dipole type radiating elements, drive voltages are applied; the resulting currents are used to calculate SEP.

$$\text{SEP} = \frac{120 F^2(\theta, \phi) \sum_{n=1}^N I_n \sum_{n=1}^N I_n^*}{N \sum_{n=1}^N I_n I_n^* R_n} \quad (20-46)$$

Here the element pattern is F and R_n is the Scan Resistance of the n th element. Note that summing fields from one element excited at a time is incorrect; the correct set of currents requires that all elements be excited.¹⁹ Measurement of SEP thus requires the array to be used as a receiver, so that all element amplitudes and phases are correct. This is easily done in a gain measurement setup, using a compact range, or an anechoic chamber. SEP is also usually validated by a computer-based simulation code, or by waveguide simulators; see below. Scan Impedance (SI), formerly called Active Impedance, is not directly measurable. Network analyzer setups excite one array element only. A method that can be used is the Load Pull method (Van Wagoner and Hansen²⁰), where in a receiving array the matching impedance for one element is adjusted for maximum received power. The SI is then the complex conjugate of this impedance. Scan Impedance, which is a function of scan angles θ , ϕ and frequencies, is important as it affects the impedance match and power transfer. Scan Element Pattern, also a function of scan and frequency, tells the radar or communications systems designer how well the system works. Note that SEP is not an antenna "pattern"; it shows gain versus scan. Figure 20-15 shows SEP for a dipole array; Figure 20-16 is for the array with a ground plane.

FIGURE 20-15 Scan element pattern, dipole array

Waveguide Simulators

Scan Impedance of an element in an infinite array can be simulated^{21,22} by placing an element, or sub-array, in a rectangular waveguide. The plane waves that compose the dominant waveguide mode simulate the array at the plane wave angle. The Scan Impedance is obtained from the reflection coefficient in the guide. Figure 20-17 shows a typical simulator in rectangular waveguide. Parts of adjacent elements are included in the unit cell. This infinite array model can predict with good accuracy the array impedance and impedance

FIGURE 20-16 Scan element pattern, dipole array with screen

FIGURE 20-17 Waveguide simulator for hexagonal lattice (after Hannan and Balfour²¹ © IEEE 1972)

variation with scan for a finite array. Even arrays of modest proportions (less than 1000 elements) have been in reasonable agreement with the results predicted for an infinite array. The reason for this is that, in practice, the mutual coupling between the elements decays as $1/x^2$, where x is the distance between the elements. Hence, the effect of mutual coupling is quite localized in cases of practical interest. All the elements with the exception of the edge elements in the array behave as though they are in an infinite array environment. For large arrays, the effect of edge elements on array performance is negligible.

On all arrays, the edge elements experience impedance changes. These effects have been modeled by a Gibbs type phenomenon.²³ Edge effects are somewhat larger for E-plane scan.^{24,25}

20.5 FEED DESIGN FOR PHASED ARRAYS

This section presents a survey of the various methods of feeding the array elements to form the required beam patterns in space. For simplicity, linear array configurations will be used as illustrations. Extrapolation to a planar array can be accomplished either with a single technique or by using a combination of two different techniques; for example, one technique for rows and the other for column. In general, most of the beamforming feeds for phased arrays can be categorized into three basic groups: (1) networks, (2) multiple beams, and (3) lenses. A description of the various types of feeds in each of these groups is given next.

FIGURE 20-18 End-fed series feeds

Network Feeds

The various types of network feeds can be classified into two groups: series feeds and parallel feeds. In each group, the feeds can be designed to provide either a single pencil beam or monopulse sum-and-difference beams. A description of the various types of feeds in each group follows.

Series Feeds

Figure 20-18 illustrates several types of series feeds. In all cases the path length to each radiating element must be computed as a function of frequency and taken into account when setting the phaser. Figure 20-18 illustrates two examples of end-fed serial feed systems in which the elements are arranged serially along the main line. They consist of a main transmission line from which energy is tapped (in the case of transmission) through loosely coupled junctions to feed the radiating elements. To steer the beam, phasers are added in either of the branch lines feeding the radiating elements, as shown in Figure 20-18a, or in the main line, as shown in Figure 20-18b. The amplitude taper is established by properly designing the couplers at the junctions. For example, if all the junction couplers are identical, the amplitude taper envelope will be approximately exponential.

Mechanical simplicity is, perhaps, the greatest advantage of these two configurations over others to be discussed. They are easy to assemble and to construct. The configurations are easily adapted to construction in waveguides, using cross guide directional couplers as junctions. They are potentially capable of handling full waveguide power at the input (within the limitations of the phaser). However, they suffer losses associated with the corresponding length of a waveguide plus that of the phasers. Perhaps the most severe limitations of this feed system is its dependence of pointing angle on frequency.

The configuration of Figure 20-18a places lower power handling demands on the phasers and also results in a lower system loss for a given phaser loss. On the other hand, the configuration of Figure 20-18b has an advantage in that all phasers will have identical phase shifts for a given pointing angle—a property which results in simplified array control. However, the total system loss of Figure 20-18b is higher than that of Figure 20-18a.

Monopulse sum-and-difference beams can be formed by feeding the array in the middle instead of from the end (see Figure 20-19a). This approach, however, would not be able to provide good sum-and-difference patterns simultaneously. For example, if the couplers in the feed are designed to provide low sidelobes for the sum pattern, the resultant pattern for

FIGURE 20-19 Center-fed series feeds with monopulse sum-and-difference beams

the difference beam would have high sidelobes. At the cost of some additional complexity, this sidelobe problem can be solved by the method shown in Figure 20-19b. Two separate center-feed feed lines are used and combined in a network to give sum-and-difference-pattern outputs.²⁶ Independent control of the two amplitude distributions is possible. For efficient operation, the two feed lines require distributions that are orthogonal to each other; that is, the peak of the pattern of one feed line coincides with the null from the other. The aperture distributions are respectively even and odd.

The bandwidth of a series feed can be increased by making the path length from the input to each output of the branch lines all equal, as shown in Figure 20-20. However, if the bandwidth is already limited by the phasers and the couplers, very little benefit can be derived from this approach at the cost of a considerable increase in size and weight. The network of Figure 20-20 simplifies the beam steering computation since the correction for path length differences is no longer necessary.

The frequency dependence associated with series feeds can be reduced by the use of parallel feeds at a cost of slightly more complex mechanical structure. The frequency dependence (or change in beam pointing angle with frequency) of parallel feed configurations depends mainly on the frequency characteristics of the phasers and the couplers at the junctions of the feed, if the line lengths from the transmitter to the elements are all made equal. Thus, if variable time-delay phasers were used in place of the constant phase type of phasers at each element, the beam-pointing angle would be essentially independent of frequency. The frequency dependence of a parallel feed using constant-phased-type phasers will be discussed later.

FIGURE 20-20 Equal-path length feed

The most common technique for realizing parallel feeds is the *matched-corporate-feed structure* of Figure 20-21. In this configuration, the corporate feed is assembled from matched hybrids (four-port junction devices with the isolated ports terminated into matched loads). The out-of-phase components of mismatch reflections from the aperture and of other unbalanced reflections are absorbed in the terminations. The in-phase and balanced components are returned to the input, and power reflected from the aperture is not reradiated. When nonreciprocal phasers (the two-way path length through the phaser is a constant independent of the phaser setting) are used in place of reciprocal phasers at each radiating element, the couplers at the junctions of the corporate feed can be reactive Tee's (three-port devices) instead of matched hybrids. In this case, however, the reflections from the aperture will add up in phase at the input to the feed. Therefore, a high power isolator must be used to protect the transmitter and/or a high power limiter be used to protect the receiver.

A method of achieving sum-and-difference monopulse beams for a parallel feed is shown in Figure 20-22. The signals from a pair of elements, which are located symmetrically opposite from the centerline of the array, are combined in a magic *T* (matched hybrid) to form their sum-and-difference signals. The sum signals from all the pairs across the array aperture are then combined in a power combiner network to form a sum beam. The desired amplitude distribution for the sum beam can be achieved by proper weighting of the signals in the power combiner network. The difference signals from all the pairs are combined in a separate power combiner network to form a difference beam. Amplitude weighting in the

FIGURE 20-21 Corporate feed

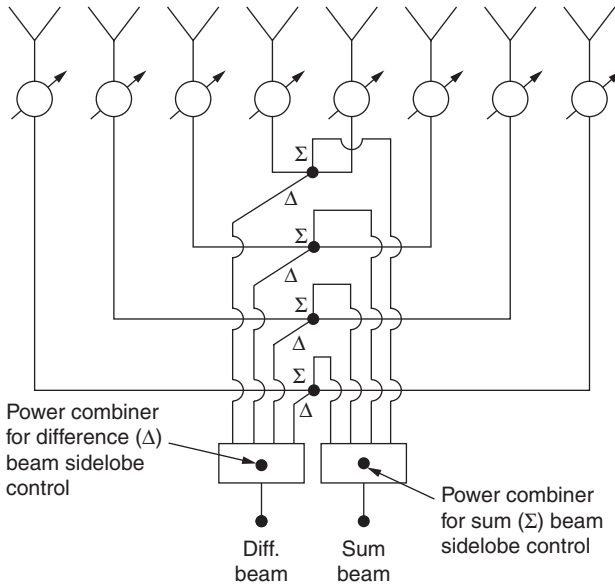

FIGURE 20-22 Constrained monopulse feed with independently controlled sum-and-difference sidelobes

two combiner networks can be made differently to obtain low sidelobes for both the sum and the difference beams. For example, the low sidelobe amplitude distribution for a sum beam is in the form of a Taylor distribution, whereas a Bayliss distribution is used for low sidelobe difference beams.⁹ By using the method, independent control of both the sum and the difference beams is achieved.

Phasers and Time Delay

A key component of many phased arrays is the phaser (or phase shifter). There are many phaser types and configurations; these are the subjects of Chapter 21. With the current interest in wideband antennas, time delay units are appropriate. (Note that all time delay is “true.”) In principle, a digital delayler could be placed at each array element, with the maximum delay of $(N - 1)kd \sin \theta$, where the (linear) array has N elements with spacing d , and scan angle θ . For a large array, each delayler must have many bits of delay. In practice a phaser with three to five bits is located at each element, with delaylers located down the feed structure. A simplistic approach of installing the smallest delay bit at the element combiners, then the next larger delay bit at the next layer of combiners, and so on, is not recommended due to the generation of high quantization lobes at some frequencies.²⁷ For wideband systems, a good arrangement locates a delay bit and phaser in one arm of a binary combiner; larger delay bits and phasers are placed in one arm of each successive combiner. For any arrangement of delaylers and phasers, extensive computer simulations are essential to insure against unacceptable QL and main beam splitting.

Each system will have 1σ amplitude and phase tolerances required to provide the desired array sidelobe and gain performance. With long arrays, a 5 or 10 deg 1σ phase tolerance may be difficult to maintain in a maximum delay of $(L/\lambda) \sin \theta$ deg., or $t_{ns} = 3.33 L \sin \theta$, where array length L is in meters. Delay lines are also lossy, so amplitude

compensation may be necessary for each larger delay bit. Frequency dispersion must always be minimized.

Multiple Beam Feeds

Another class of constrained feeds for phased arrays consists of the multiple beamforming feed network. These feeds can generate multiple simultaneous beams covering a large sector of space. For the same beam-pointing direction, each beam has essentially the gain of a single-beam array of the same size and illumination except for a possible increase in RF circuit losses over a single beam array. A separate beam terminal is provided for each beam of the multiple beamforming feed network.

Butler Matrix

A widely used multiple beam antenna is the Butler matrix.²⁸ As sketched in Figure 20-23, the number of beam ports equals the number of element ports; both are a power of two. The connecting transmission lines are interconnected by 90 degree hybrids. Fixed units of phase provide the proper phase front for each beam. The many unconnected crossovers make implementation more difficult. Note that if the phase units are replaced by equivalent time delay units, the Butler bandwidth decreases.

A signal injected at any of the beam input terminals excites all the radiating elements equally in amplitude, with phase differentials of odd multiples of $180^\circ/N$, where N is the total number of radiating elements or beam terminals. The array patterns of the beam generated are of the form $\sin Nx / \sin x$ since the amplitude taper is uniform. Specifically, they are

$$E_m(v) = \frac{\sin \frac{N}{2} \left[kd - (2m+1) \frac{\pi}{N} \right]}{\sin \frac{1}{2} \left[kd - (2m+1) \frac{\pi}{N} \right]} \quad (20-47)$$

FIGURE 20-23 Butler matrix beamformer (after Hansen³ © Wiley 1998)

with N main beams completely covering one period of v . The beams specified by Eq. 20-47 cross over at a relative amplitude of $2/\pi$ (-3.92 dB), and the peaks of the beams are located at the nulls of the other beams. Since these beams are orthogonal to each other, there is no cross-coupling loss between beams. As expected from Eq. 20-47, as the frequency changes the beam positions change, although the individual beamwidths do not. At twice the design frequency the rosette of beams occupies ± 45 deg. And at half the design frequency the rosette of beams contains only half of the beams; the rest are in “invisible space.” Butler matrices can be stacked and cascaded to form a 2-D rosette of beams. There is also a 2-D Butler-type matrix based on a hexagonal array with hexagonal element lattice.³

Rotman Lens

Another popular multiple beam antenna is the Rotman Lens.²⁹ It consists of a flat 2-D wave guiding medium such as parallel plate waveguide, stripline, or microstrip. A set of beam ports is located on a concave arc, and a set of element ports is located on an opposing concave arc; see Figure 20-24. The arcs are generally of different shapes, and the number of beam ports is typically not equal to the number of element ports. From each element port, a specified length of transmission line connects to the radiating element. There are six basic design parameters, and these may be optimized for a given application. In principle, the Rotman lens can have three perfect foci: one on center line and two symmetrically located. In practice the best design provides minimum error in least squares sense. There is more information on design trades in the references.³⁰

Frequency behavior is the opposite of that of the Butler matrix antenna. For the Rotman lens, the beam positions are fixed by the geometry. As frequency deviates from the design frequency, the individual beams become narrower or wider. Beam crossover levels change accordingly.

FIGURE 20-24 Rotman lens beamformer (after Hansen³⁰ © IEEE 2002)

Bootlace Lens

Illumination of the array elements in a space-fed antenna is accomplished by optically distributing the source signal (transmitter) through space. This illuminates an array of pickup horns (elements) which are connected to the radiating elements. The advantage of a lens beamforming feed over the network system is simplicity. Disadvantages are a lack of amplitude tapering control and an excessive volume of physical space required to accommodate the feed system. Two basic types of bootlace lens feeds, the transmission type and the reflection type, are shown in Figure 20-25.

In the transmission type, the array elements are the radiating space elements of a feed-through bootlace lens, as shown in Figure 20-25a. These radiating elements are coupled to the pickup elements of the feed-through lens by phasers. Both surfaces of the lens require matching to optimize performance. The pickup surface is illuminated by a primary feed placed at a focal distance f behind the lens. The radiation pattern of the primary feed must be optimized to provide an efficient aperture illumination with little spillover loss. If desired, separate transmit and receive feeds may be used, with the feeds separated by an angle α as shown in Figure 20-25a. The antenna is then rephased between transmitting and receiving so that in both cases the beam points in the same direction. The phasing of the antenna must include a correction for the spherical phase front of the feed. The required phase correction is given by

$$\phi_c = \frac{2\pi}{\lambda} (\sqrt{f^2 + r^2} - f) = \frac{\pi}{\lambda} \frac{r^2}{f} \left[1 - \frac{1}{4} \left(\frac{r}{f} \right)^2 + \dots \right] \quad (20-48)$$

With a sufficiently large focal length, the spherical phase front may be approximated by that of two crossed cylinders, permitting the correction to be applied simply with row and column steering commands. The correction of the spherical phase front can be accomplished by the phasers. Space problems may be encountered in assembling an actual system, especially at high frequencies, since all control circuits must be brought out at the side of

FIGURE 20-25 Bootlace lenses

the aperture. Multiple beams may be generated by adding additional primary feed horns. All the multiple beams will be scanned simultaneously by equal amounts in $\sin \theta$ space. Monopulse sum-and-difference patterns may be generated by taking the sum and difference of two adjacent multiple beams with a magic T or by using multimode feed horns.

In the reflection type, the phased array aperture is used as a reflector, as shown in Figure 20-25*b*. The same radiating element collects and reradiates the signal after it has been reflected from the short circuits terminating the phasers. The phase of the reflected signal is determined by the phaser setting. The phaser must be reciprocal so that there is a net controllable phase shift after the signal passes through the device in both directions. The requirement rules out nonreciprocal phasers. Ample space for phaser control circuits exists behind the reflector. To avoid aperture blocking, the primary feed may be offset as shown. As in the case of a transmission lens, transmit and receive feeds may be separated and the phases separately computed for the two functions. Multiple beams are again possible with additional feeds.

The lens surfaces in Figure 20-25 are flat; if the feed face and the array faces are circular arcs, and if the phasers are replaced by delayers, the lens bandwidth will be significantly improved.

All of the previous information concerns a 1-D bootlace lens with a linear array. Bootlace lenses feeding a planar array are the same in principle. However, a 2-D lens such as the Rotman lens, or a 2-D version of Figure 20-24, can have three perfect focal points. But rotating the 1-D lens does not rotate the foci into circles. A 2-D lens can have up to four foci, but they are generally in one plane, with the result that performances are poorer in the cross plane. Also this requires ellipsoidal faces.³ A 2-D bootlace with spherical cap feed and element port faces will have a modest performance; use of delayers will increase the bandwidth, but off-axis performances will be degraded.

Digital Beamforming

The slow but steady increase in bit-bandwidth product of A/D converters has rekindled interest in digital beamforming for receiving arrays. In such arrays, the output of each element is amplified and filtered as necessary, and then fed to an A/D converter. Or the down converted signal can be sampled, often on the I and Q signals.³¹ Beam scanning, multiple beams, monopulse beams, and sidelobe control are performed digitally. The inter-element delay is

$$\tau = (d/c) \sin \theta_0 \quad (20-49)$$

Where d is the interelement spacing, θ_0 is the beam angle, and c is the velocity of light. Using Nyquist sampling of two samples per cycle, the sampling interval T is

$$T = \lambda / (2c) \quad (20-50)$$

These two times are, in general, not integer multiples of each other. Only certain beam angles allow the beam steering delay values. The most common solution to this dilemma is over sampling. A high rate of over sampling is usually needed to provide many beam positions. Interpolation filtering is followed by summing over a window of time samples and over the array elements.³² An alternate solution interchanges the beamforming and interpolation filtering procedures.

Beamforming can also be performed in the spectral domain, with the advantage that delays become phase multipliers.³³ An FFT is performed on the output of each element, with each output multiplied by $\exp(j\omega\tau)$. Summing yields a beam in frequency. An inverse FFT then provides angular beams in time.

Bandwidth of Phased Arrays

The bandwidth of a phased-array antenna depends upon the types of components, such as elements, phasers, and feed networks, which comprise the array. In practice, most elements for phased arrays are matched over a broad band of frequencies. Therefore, the element design is not a primary factor in the determination of bandwidth. The limitations on bandwidth are determined by the frequency characteristics of the phasers and feed networks.^{34,35} In general, the effects due to the phasers and feed networks are additive, so that if the phaser causes the beam to scan by an amount equal to $\Delta\theta_p$ and the feed causes the beam to scan by $\Delta\theta_f$, then the total beam scan is given by $\Delta\theta_p + \Delta\theta_f$. To establish the bandwidth capability of a phased array, these two effects must be examined. There are more details concerning the bandwidth limitations of phased arrays not covered in this book.³

Phaser Effects

To evaluate the effects caused by the phaser alone, a corporate feed (equal line length parallel feed) is used to illuminate all the radiating elements (see Figure 20-21). This corporate feed exhibits no feed effects since a signal at the input illuminates all the elements with the same phase regardless of frequency. The bandwidth in this case is completely determined by the type of phaser used in the array. In this discussion, consider the effects of two basic types of phasers: (1) time delay phasers and (2) constant phase-type phasers. A detailed description of these two types of phasers is given in Chapter 21.

When delayers are used at each element, the signals received by the elements from an incident wavefront at an angle θ_0 are appropriately time delayed so that they all arrive at the output terminal of the corporate feed at the same time. For example, the amount of time delay at the first element of the array shown in Figure 20-21 is equal to the additional time required for the wavefront to travel to the last element after arriving at the first element. This time delay T , known as aperture fill time, is given by

$$T = \frac{L}{c} \sin\theta_0 \quad (20-51)$$

where

L = total length of array aperture

c = velocity of light

θ_0 = angle of incidence of wavefront from array normal

In this case, the phase distribution across the array aperture produced by the time delay feed matched that of the incident wavefront independent of frequency. Consequently, the beam position remains stationary with frequency change, and the array has infinite bandwidth. When the angle of incidence of the incoming wavefront changes, the number of delays at each element must be changed accordingly, in order to maintain the bandwidth. The previous discussion is valid for either a CW or a pulsed incidence signal. For the pulsed incidence signal, the time-delay feed preserves the shape of the pulse without any distortion.

When constant phase-type phasers (phasers whose phase shift is independent of frequency) are used at each element, the output phase distribution of the feed matches that of the incident phase front *only* at *one* frequency f_0 and for a particular incidence angle θ_0 . At a different frequency f_1 , the output phase distribution of the feed network remains fixed; hence the array is phased to receive at a different incidence angle θ_1 . The amount of beam squint with frequency is given by the following relationship:

$$f_1 \sin\theta_1 = f_0 \sin\theta_0 \quad (20-52)$$

For a small change in frequency, Eq. 20-52 shows that the change in scan angle is given by

$$\Delta\theta_0 = -\left(\frac{\Delta f}{f}\right)\tan\theta_0 \quad (20-53)$$

The previous expression shows that the amount of beam squint depends upon the original scan angle as well as on the percent frequency change. At broadside ($\theta_0 = 0$), there is no scanning, regardless of the amount of change in frequency, and the array has infinite bandwidth. When the beam scans away from broadside, the amount of beam squint with frequency increases with scan angle. Therefore, the bandwidth of an array must be specified in terms of the desired maximum scan angle. For most practical applications, the desired maximum scan angle is $\pm 60^\circ$ from array broadside. If we assume that the maximum allowable beam squint is ± 1 quarter beamwidth away from the desired direction, corresponding to a one-way gain loss of 0.7 dB, the bandwidth of the array is given by

$$\text{Bandwidth (percent)} = \text{beamwidth}(\circ) \quad (20-54)$$

Series Feed Effects

When a feed other than an equal length parallel feed is used, phase errors due to the feed alone are produced across the array aperture. An example is the series feed shown in Figure 20-18*b*. The total phase shift across the length of the feed is $\Phi = (2\pi/\lambda)L$ rad with free space propagation assumed. When the frequency is changed, the change in phase across the array aperture will be

$$\Delta\Phi = \frac{2\pi L}{c}\Delta f \quad (20-55)$$

This linear change in phase across the aperture scans the beam just as phasers would. To observe just how far the beam is scanned, examine the way in which an aperture is scanned with phase. For a given scan angle θ_0 the required phase across the array is

$$\psi = \frac{2\pi L}{\lambda}\sin\theta_0 \quad (20-56)$$

The required change in ψ for a change in scan angle is

$$\frac{d\psi}{d\theta} = \frac{2\pi L}{\lambda}\cos\theta \quad (20-57)$$

or

$$\Delta\psi = \frac{2\pi L}{\lambda}\cos\theta_0\Delta\theta_0 = \frac{2\pi Lf}{c}\cos\theta_0\Delta\theta_0 \quad (20-58)$$

when the change in phase across the array is induced by the feed, $\Delta\psi = \Delta\Phi$, or

$$\frac{2\pi L}{c}\Delta f = \frac{2\pi Lf}{c}\cos\theta_0\Delta\theta_0 \quad (20-59)$$

Hence the amount of beam scan for a change in frequency is given by

$$\Delta\theta_0 = \left(\frac{\Delta f}{f}\right)\frac{1}{\cos\theta_0} \quad (20-60)$$

For beams scanned in the direction of the feed load, the phase change between the elements due to the feed line is partially offset by the required phase change needed to maintain the beam position at a given scan angle θ_0 . In fact, for an endfire beam toward the load, the required phase change with frequency needed to maintain the beam at end free is exactly the same as that due to the feed line. Hence, the bandwidth of a series feed at the end-free beam position toward the load is infinite. However, this endfire beam position is not practical to implement because of the drastic reduction in the gain of the radiating elements. Furthermore, in most applications the array is required to scan in both directions from broadside. For beams scanned in the direction of the feed input, the phase changes in space and the feed line become additive, instead of canceling each other. As a result, the beam scans rapidly with frequency. For a 60° scan angle, the scanning caused by the feed alone is slightly greater than that caused by the aperture. Therefore, the bandwidth of the series feed is essentially half of that of the equal line length parallel feed.

In waveguide, the signal propagates more slowly; this is equivalent to having a longer feed line. This causes the feed to scan more rapidly, and the series feed performance degrades accordingly. The slowing in waveguide is proportional to λ/λ_g , and the array scans by

$$\Delta\theta \cong \frac{\lambda_g}{\lambda} \left(\frac{\Delta f}{f} \right) \frac{1}{\cos\theta_0} \text{ rad} \quad (20-61)$$

For $\pm 60^\circ$ scanning from broadside, the bandwidth of a series feed under the same conditions as that of a parallel feed is given by

$$\text{Bandwidth (percent)} = \frac{1}{\left(1 + \frac{\lambda_g}{\lambda} \right)} \text{ beamwidth } (^\circ) \quad (20-62)$$

A center-fed series array,³⁶ as shown in Figure 20-26a, may be thought of as two end-fed series arrays. At band center the phase shifters are set so that all the elements radiate in phase. As the frequency is changed, each half scans in the opposite direction because of the gabled phase slope, as shown in Figure 20-26b. For the broadside beam case, this results in a broadening of the beam with no change in direction. If the two beams were to move far enough apart (Figure 20-27), the beams would split. However, by restricting the bandwidth to reasonable values, the result is a loss in gain caused by the beam broadening.

When the array is scanned away from broadside, aperture scanning due to the phaser (constant phase with frequency) is also introduced, and it is superimposed on the feed scanning. As shown in Figure 20-27 for one-half of the array (solid curve) aperture scanning and feed scanning tend to cancel each other, while for the other half (dashed curve) they tend to reinforce each other. The performance of the center-fed array is worse than that of the parallel-fed array at broadside but quite comparable at large scan angles. At a scan angle of 60° , the center-fed array will have approximately $\frac{1}{4}$ dB more loss than the parallel-fed array. For simplicity, the same bandwidth formula Eq. 20-54 can be used for both feeds.

The previous discussion has assumed that the center feed used nondispersive transmission with free-space propagation. If waveguide is used, the performance of the center-fed array degrades and the bandwidth is given by

$$\text{Bandwidth (percent)} = \left(\frac{\lambda}{\lambda_g} \right) \text{ beamwidth } (^\circ) \quad (20-63)$$

Amplitude and phase errors also affect sidelobes.^{37,38}

21.1 INTRODUCTION

While there are a myriad of applications for microwave phase shifters in instrumentation and metrology, power combining, amplifier linearization, and so on, the most prevalent use is in scanning phased-array antennas. And while this market continues to be dominated by military radar and tracking platforms, many commercial applications have emerged in the past decade or so. These new and potential applications span low Earth-orbiting communications satellite constellations and collision warning radar, an aspect of the Intelligent Vehicle Highway System or Automated Highway System. In any case, the phase shifters represent a considerable portion of the overall antenna cost, with some estimates approaching 40 percent for receive arrays. Ferrite phase shifters continue to be the workhorse in military-phased arrays, and while there have been advances in thin film ferrite devices, the review of this device technology in the previous edition of this book is still highly relevant. This chapter will focus on three types of phase shifters that have matured in the past decade: GaAs MESFET monolithic microwave integrated circuit (MMIC), micro-electromechanical systems (MEMS), and thin film ferroelectric-based devices. A brief review of some novel devices including thin film ferrite phase shifters and superconducting switches for phase shifter applications will be provided. Finally, the effects of modulo 2π phase shift limitations, phase errors, and transient response on bit error rate degradation will be considered.

Applications

Military applications emphasize ground-based systems for early warning radar, missile defense, and space surveillance. Most of the systems employ ferrite phase-shifter technology, but several examples of GaAs MMIC-based arrays exist. Space applications, including civilian space applications, include synthetic aperture radar and satellite communications. Another burgeoning commercial application is collision warning and collision avoidance radar for the Intelligent Vehicle highway System.

Military Phased Array Antennas Table 21-1 summarizes some of the military phased array radar systems.^{1,2} Note that many of the arrays developed during the last three decades had production runs of over 50 and that even one radar system can necessitate a very large number of phase shifters.

The last two systems use MMIC modules. The Theater High Altitude Area Defense (THAAD) ground-based radar required over 60,000 MMIC phase shifter chips. The program demonstrated a per-module cost of about \$1,000. The Counter Battery Radar (COBRA) artillery and mortar weapon-locating system required more than 8000 MMIC modules.

Commercial Satellite Communications Customers for commercial satellite services include remote or mobile data-intensive professionals requiring fast downloading and uploading capabilities. Example users are banks, businesses using video-conferencing, oil drilling platforms, medical evacuation helicopters, airliners, cruise ships and the like. In developing countries, where a communications infrastructure is close to nonexistent, corporations are in need of ways and means to communicate. However, the greatest growth in demand may be fueled by consumer (residential) requirements such as: distance learning, electronic mail, home shopping, telecommuting, and entertainment services such as high definition television and video phones. Compared to geostationary (GEO) satellites, LEO satellites offer at least three major advantages. First, they orbit at an altitude generally below 1000 km instead of about 35,000 km. Since signal loss is proportional to distance squared,

COBRA	C	3	2,700	8,100	Lockheed

an automatic power savings of about 30 dB occurs. This permits substantially smaller Earth terminals. Second, their proximity provides a nearly imperceptible propagation delay just like terrestrial systems, instead of the 0.25 second delay associated with GEO satellites. While this may be nothing more than a nuisance for voice services, it causes technical problems with higher data rates (for example, computer networking) and handshaking (for example, ATM switching). Third, there is potential for significantly reduced launch costs. For practical, aesthetic, or technical (agility and reliability) reasons, scanning phased arrays seems to be the lynchpin. System architectures tend to place considerable burden on the space segment, allowing the use of relatively small (for example, < 1 m) Earth terminals, to support data rates from perhaps 2.048 to 155.53 MBPS. These quixotic visions have yet to be realized, but could become tractable given a *low-cost* phased array solution.

There are also high data rate geostationary (GEO) platforms such as Spaceway (Hughes). Mobile platforms requesting service need some type of articulated antenna to track the satellite, both because of variable latitude and longitude, and to compensate for pitch, roll, and yaw. Again, the low-cost phased array seems an elusive solution.

Automated Highway Systems At the turn of the millennium, there were about 140 million automobiles just in the United States. As populations grow, highway traffic expands, but construction costs and available real-estate prevent the highway system from keeping pace. The Intelligent Vehicle Highway System, especially in the context of intelligent cruise control, collision avoidance radar, and electronic tolling is a solution to optimize traffic flow and reduce flawed decision making. For a collision warning application, the phased array can be relatively small. Preliminary specifications suggest an operating frequency of 77 GHz with a 1.5° by 6° beamwidth, a 10 Hz scan rate, and 10 mW output power.³ Electronically-steered arrays enhance collision avoidance radar both because of the beam-pointing precision requirements and the need to essentially see around corners.

The specified transmitter power corresponds to a timely warning for detecting a human, with a 1 m² radar cross-section, at a 300 m range.⁴

Phase Shifter Characteristics Evolving high data rate communications systems demand greater attention to subtle aspects of information theory and electromagnetic engineering. As the ratio of signaling bandwidth to carrier frequency decreases, less familiar phenomenon can influence system performance. And, new coding techniques are pushing channel capacity ever closer to the Shannon limit.⁵ Some interesting effects are expected to appear if the trend toward wide-band scanning phased array antennas and efficient high-speed modulators continues.⁶ For example, in a phased array antenna inter-element spacing, the physical size of the array, and the steering vector can conspire to introduce pulse distortion from group delay, inter-symbol interference, and beam squinting.^{7,8} And the operating point of the amplifiers can affect the bit error rate depending on the modulation type and the number of carriers. Naturally one wants the phased array to operate as efficiently as possible given power limitations and thermal management problems. This desire necessitates that the power amplifiers operate in a nonlinear region near saturation. Nonlinear effects cause amplitude-to-amplitude modulation (AM/AM) and amplitude-to-phase modulation (AM/PM) distortion. The net effect of AM/AM distortion is to alternately compress and expand the signal constellation. The net effect of AM/PM conversion is a rotation of the signal constellation.⁷ In a receive array, the third order intercept of the low noise amplifiers largely determines inter-modulation distortion and heat dissipation.⁹ But the phase shifter insertion loss envelope and phase accuracy are also key factors influencing array performance. Phase shifters typically follow low noise amplifiers in a receive array and precede power amplifiers in a transmit array. Since the phase shifter's insertion loss depends on its phase setting and since its switching action represents some finite time domain response, its potential contribution to bit error rate degradation cannot generally be ignored. There will always be some effects in any phase-shift keyed (PSK) modulation system, the degree to which depends on the steering vector update rate and data rate. A long switching time also increases minimum radar range. Besides these issues, the satellite communication market's desire to install tracking terminals on commercial mobile platforms, even at small office/home office and residential sites, has inspired the search for inexpensive phase shifters and affordable phased arrays. In practice, system constraints on chip size, power handling, drive power, insertion loss, bandwidth, phase error, transient response, and cost dictate particular device designs.

21.2 SEMICONDUCTOR

Semiconductor phase shifters, based primarily on GaAs, but also on SiGe and InP, have enjoyed steady progress for the past two decades. Their small size and relatively low power consumption compared to ferrite devices has created new insertion opportunities. Many possible circuit topologies, using diode or FET switches in various configurations, exist.

High-Pass/Low-Pass

In principle, any variable reactance in series or shunt across a transmission line can be used to introduce phase shift. A high-pass/low-pass phase shifter π network using discrete capacitors and inductors is shown in Figure 21-1. In the high-pass configuration shown, a relative delay is realized. In the opposite configuration, with all SPDT switches toggled, the low-pass circuit represents a relative phase advance.¹⁰ It can be shown that if the circuit is matched, $X = 2B/(1 + B^2)$ and the insertion phase is $\tan^{-1}(2B/(B^2 - 1))$.¹¹ The switches can be implemented with PIN diodes or MESFETs, which will be discussed later on in this section. It is possible to realize a phase shift of 180° with about 20% bandwidth.

FIGURE 21-1 Topology for a high-pass/low-pass π network phase shifter. A dual “T” network realization is also possible.

Loaded Line

Another type of phase shifter generally used for achieving 22.5 to 45 degrees of phase shift is the loaded-line.¹² A schematic of this is shown in Figure 21-2. Ideally, reactive loads spaced one-quarter wavelength apart across a transmission line to effect phase shift. The purpose of the second shunt susceptance (jB) is to cause a reflection, which will at least partially cancel the reflection from the first shunt susceptance (jB).

By equating the ABCD matrix of Figure 21-2 to an equivalent section of transmission line with electrical length θ_L radians and characteristic impedance Z_0 Ohms as given in Eq. 1,

$$\begin{pmatrix} 1 & 0 \\ jB & 1 \end{pmatrix} \begin{pmatrix} 0 & jZ_0 \\ j/Z_0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ jB & 1 \end{pmatrix} = \begin{pmatrix} \cos(\theta_L) & jZ \sin(\theta_L) \\ j\sin(\theta_L)/Z & \cos(\theta_L) \end{pmatrix} \quad (21-1)$$

we obtain

$$Z = Z_0/[1 - (BZ_0)^2]^{1/2} \quad (21-2)$$

and

$$\theta_L = \cos^{-1}(-BZ_0) \quad (21-3)$$

If the susceptance is capacitive, the phase velocity is decreased; if the susceptance is inductive, the phase velocity is increased. Loaded line phase shifters are inherently

FIGURE 21-2 Loaded-line phase shifter

narrow-band and produce a constant phase shift versus frequency response. The phase versus frequency response is generally not as flat as the high-pass/low-pass type.

Switched Line

The switched-line phase shifter is yet another popular type, and is intuitively easy to understand. SPDT switches are used to toggle between transmission lines with different path lengths. As opposed to the types discussed previously, this one is a true time-delay device. That is, it provides a phase response (φ) proportional to frequency (ω). Since time delay, $\tau = -d\varphi/d\omega$ and φ is proportional to ω , τ is a constant over the bandwidth. A schematic is shown in Figure 21-3.

The differential phase shift is

$$\Delta\varphi \approx \beta(L2 - L1) \quad (21-4)$$

where β is the propagation constant of the transmission line. As usual, β equals the radian frequency ω divided by v_p , where v_p is the phase velocity. A point of caution needs to be made with regard to this design, however. Utilizing series diode switches, it is possible that the off path length and switch capacitance can conspire to create a through path in parallel with the on path, resulting in high insertion loss and abrupt phase change in band. Utilizing MESFETs in place of the SPDT switches shown, the on path could also experience high loss under certain conditions. If the MESFET is treated as a very small resistance in series with a pinch-off capacitance of 0.1 pF, the insertion loss (and phase) of the “on” path, say $L2$, will vary as shown in Figure 21-4 with $L2$ as a parameter.

The higher loss with increasing $L2$ is predominantly due to interaction with the switches, not dissipative loss. So $L1$ and $L2$ must be chosen with deference to the switch characteristics.

A photograph of a 4-bit GaAs monolithic phase shifter is shown in Figure 21-5.¹³ The chip size is approximately $5.5 \times 2.5 \times 0.15 \text{ mm}^3$. The 180° , 90° , and 45° bits are implemented using the switched line approach, whereas the 22.5° bit is realized with a loaded line. The operating frequency was 30 GHz with about a 10 percent bandwidth. Average insertion loss was <10 dB with an insertion loss envelope of about 2 dB.

FIGURE 21-3 Switched-line phase shifter. Signal path is through the delay transmission line with the switches set as shown.

FIGURE 21-4 Modeled insertion loss and phase with path L2 as a parameter. The solid line is loss, and the dashed line is phase.

Beam Squint A clear advantage of a constant time-delay is that beam steering is independent of frequency. For simplicity, consider a linear array of N elements separated by distance d .¹⁴ The incremental phase shift between adjacent elements to form the beam at an angle θ from boresight is

$$\Delta\phi = (-2\pi d/c) f \sin(\theta) \quad (21-5)$$

where f is frequency and c is the speed of light in vacuum. If the frequency changes by Δf , the beam squint angle $\Delta\theta$ and phase deviation $\delta\phi$ are related by

$$(\Delta\phi + \delta\phi) = (-2\pi d/c) (f + \Delta f) \sin(\theta + \Delta\theta) \quad (21-6)$$

FIGURE 21-5 30 GHz GaAs MMIC phase shifter using $1 \times 400 \mu\text{m}$ switching FETs. The chip size is $5.5 \times 2.5 \times 0.15 \text{ mm}^3$ not including off-chip capacitors (after J. Geddes et al¹³ © IEEE 1987).

If the phase shifter insertion phase is proportional to frequency, the beam squint $\Delta\theta$ is zero. If the phase is independent of frequency, however, $\delta\phi$ is zero and equations (5) and (6) must be equal, yielding

$$f \sin(\theta) = (f + \Delta f) \sin(\theta + \Delta\theta) \quad (21-7)$$

which causes a beam squint angle

$$\Delta\theta = -\theta + \sin^{-1}[\sin(\theta)/(1 + \Delta f/f)] \quad (21-8)$$

Hence, wide scan angles and wide bandwidths correspond to significant scanning errors. In practice, phase shifters generally provide 0 to 2π phase shift. In electrically large arrays, the integer portion N of total delay required for true-time delay beam steering may be omitted, resulting in degraded performance. In radar systems, where narrow pulses are required for high resolution, there is a correspondingly wide frequency spectrum. The effect of this modulo- 2π problem is considered in detail later in this chapter.

Digital Control The distribution of amplifier and phase shifter control signals in a large phased array is a complex problem. Thousands of MMIC modules must be interconnected into the beam forming manifold. Some type of digital interface circuitry must be used to address individual phase shifters and decode their control signals. The multiplexed data rate to accommodate fast scanning may approach a Gb/s.¹⁵ In one instance, a GaAs optoelectronic integrated circuit was used to detect and demultiplex an optical serial control signal into 16 parallel electrical signals.¹⁶ Operation of a Ka-band, 4-bit phase shifter at 30 MHz clock speeds was demonstrated. Average optical power was 250 μ W. In another instance, optically controlled switching and X-band phase shifting was demonstrated such that the optically controlled GaAs FET interacted directly with the microwave signal.¹⁷ The FET was illuminated by the focused output of a 5 mW, 670 nm, InGaAlP laser diode.

Switching Q Key requirements for microwave phase shifters include bidirectional (or reciprocal) functionality, low power dissipation, and low insertion loss. The insertion loss of the switched line phase shifter in the previous section depends on the SPDT switch loss and transmission line loss. As we have seen, an SPDT switch can be realized by several possible combinations of SPST switches. Basically, the switch is intended to minimize insertion loss in one state and maximize isolation in the other. There are two fundamental configurations for SPST switches: as a series impedance or a shunt admittance. These are illustrated in Figure 21-6.

Defining insertion loss as the ratio of available power delivered by the generator, to the load in the absence of the switch, to the actual power dissipated by the load in the presence

FIGURE 21-6 Equivalent circuit for series (a) and shunt (b) single pole, single through switch. The switch impedance and admittance are $Z_{sw} = R_{sw} + jX_{sw}$ and $Y_{sw} = G_{sw} + jB_{sw}$, respectively.

of the switch, the insertion loss for the series (L_{se}) and shunt (L_{sh}) switch is

$$L_{se} = 20 \log \left| 1 + \frac{R_{sw} + jX_{sw}}{2Z_o} \right| \text{ dB} \quad (21-9a)$$

$$L_{sh} = 20 \log \left| 1 + \frac{(G_{sw} + jB_{sw})Z_o}{2} \right| \text{ dB} \quad (21-9b)$$

In general, Z_{sw} and Y_{sw} , and Z_o for that matter, are frequency dependent. The swing in Z_{sw} and Y_{sw} determine insertion loss and isolation. Of course, the diodes and MESFETs used to realize the switches are inherently nonlinear. Diodes are forward- and reverse-biased, in order to produce the maximum possible change in impedance. In the forward bias state, the impedance is small, but the diodes conduct substantial dc current. In the reverse bias state, a depletion region is formed. It's worth noting that according to well-accepted theories for junction capacitance C_j , as forward bias is increased, C_j grows unbounded. Of course, capacitance is a measure of stored charge, and as the depletion region shrinks towards zero dimension, the stored charge diminishes towards zero.¹⁸

GaAs MESFET devices have replaced diodes in many switching applications. Monolithic integration advantages and lower power consumption are incentives. A FET is basically a gate voltage controlled resistor. Insertion loss is largely dictated by channel resistance, and gate-to-source capacitance determines isolation. To increase isolation (high impedance off state), a short (inductive) section of a transmission line is connected between the source and drain to resonate out the pinch-off capacitance C_{off} .^{19,20} Ideal equivalent circuit models for on and off FETs are shown in Figure 21-7.

The resistor R_s is the total series resistance at pinch-off (undepleted channel resistance plus source and drain contact resistance). Sokolov²⁰ defined a figure of merit (Q) for switching FETs based on the work of Kurokawa and Schlosser²¹ for a device switching between two impedance states Z_1 and Z_2 , such that

$$Q^2 = \frac{|Z_1 - Z_2|^2}{r_1 r_2} = \frac{(R_{on} - R_s) + (\omega C)^{-2}}{R_{on} - R_s} \quad (21-10)$$

Here, r_1 and r_2 are the resistive components of the two impedance states. For the FET switch, $Z_1 = R_{on}$ and $Z_2 = R_s - j(\omega C_{off})^{-1}$. Assuming $(R_{on} - R_s) \ll (\omega C_{off})^{-1}$, a good approximation to Eq. 10 is

$$Q^2 = (R_{on} R_s)^{-1} (\omega C_{off})^{-2} = R_{off} / R_{on} \quad (21-11)$$

FIGURE 21-7 Ideal equivalent circuits for on and off FETs. The inductor L is a short section of a transmission line used to parallel resonate the RC combination in order to enhance the high impedance state.

Notice that Q degrades as the square of frequency. A high figure of merit requires small R_{on} , R_s , and C_{off} . Scaling the gate width allows a trade off between isolation and insertion loss. If the gate width is doubled, R_{on} and R_s are halved, C_{off} is doubled, and Q is invariant. Typical values of Q^2 at 10 and 30 GHz are about 1000 and 100, respectively. In normal operation, no bias is applied to the drain. A negative bias on the gate (relative to the source) pinches off the channel. Zero or positive gate bias turns the channel on. Additional information on switching Q and its relationship to loss is provided in the reference section.^{22,23}

21.3 THIN FILM FERROELECTRIC

Serious research on bulk (waveguide) ferroelectric phase shifters began in the 1960s but poorer performance in comparison to ferrite devices, coupled with very high tuning voltages, forestalled industrial acceptance. New thin film deposition techniques and novel circuit designs in the 1990s heralded a new generation of devices rivaling their semiconductor counterparts in essentially every figure-of-merit.

Materials and Basic Properties

In a ferroelectric material, such as $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$, applying a dc electric field shifts the position of the central Ti atom in the crystal, resulting in a net dipole moment on a macroscopic scale (ionic polarization). Analogous to ferromagnetic materials, domains form in the material where the dipoles are locally aligned (orientational polarization). The Ti ion can remain shifted even after the applied field is removed, and the domains can move in response to applied ac and dc fields. Microwave phase shifters are generally operated above the Curie temperature, in the paraelectric state. Ideally, this means operating without residual polarization and domain formation, thereby reducing hysteresis and dielectric loss. The Curie temperature, which represents a phase change to a nominally cubic crystal lattice, can be tailored for a specific operating temperature by adjusting the composition of $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$ (BST), where $0 < x < 1$, and for room temperature $x \approx 0.60$. Interest in ferroelectric-based agile microwave circuits is mounting because of their high power handling capability, negligible dc power consumption, and potential for low loss and cost. The ferroelectrics discussed here belong to the perovskite crystal family. The dielectric constant (ϵ_r) of single crystal SrTiO_3 , an incipient ferroelectric, can be depressed from about 20,000 to 2000 with a dc field of 10^4 V/cm at 4.4 K (breakdown voltage for the materials of interest here is $>10^5$ V/cm) and the loss tangent maintained below 0.1%. Thin films of SrTiO_3 exhibit $\tan\delta$ as poor as 0.01 with a peak relative dielectric constant of ≈ 5000 . The dielectric constant also tends to exhibit a broad maximum with temperature as opposed to bulk material. The differences in behavior have been attributed to residual domain wall motion, compositional inhomogeneities, interface layers between the film and electrodes, and lattice mismatch induced stress. Fundamental loss mechanisms have been considered in some situations.²⁴ Attempts to reduce $\tan\delta$ have included annealing, which tends to increase grain size, and the use of dopants, which may reduce free charge or otherwise affect loss mechanisms.^{25–27}

Several ferroelectric phase shifters have been developed with varying success. A stripline circuit with a BST capacitor provided a differential phase shift of 11° at X-band with a biasing field of 70 kV/cm.²⁸ In that same work, a center-wire bias waveguide phase shifter produced more than 360° of phase shift at Ku-band by changing the bias between the wire and waveguide walls from 0 to 2500 V. A planar microstrip phase shifter was reported that provided $20^\circ/\text{kV}$ at 2.65 GHz.²⁹ A phase shift of 165° at 2.4 GHz with only 3 dB loss and a bias of 250 V was obtained from a microstrip on a thin BST slab synthesized using a sol-gel technique.³⁰

There was also a 40 GHz phased array antenna that used radiating slots in waveguide and a BST film sintered onto a MgO substrate.³¹ Voltage applied across a periodic set of electrodes changed the dielectric constant of the BST from 700 to 1500 and a $\tan\delta$ of 0.05 was reported. A ferroelectric lens that uses BST slabs sandwiched between conducting plates was also proposed.³² The approaches advanced thus far have not been able to simultaneously address low cost, low loss, and small size. And in some cases, the impedance variation, due to widely changing permittivity, posed additional difficulties. Two promising implementations include coupled line and synthetic line-based devices, to be discussed next.

Coupled Microstripline

Another style of phase shifter uses coupled microstriplines as dc electrodes to polarize a thin ($\approx 0.4 \mu\text{m}$) ferroelectric film. With $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ electrodes and $2.0 \mu\text{m}$ thick SrTiO_3 films, this phase shifter produces a figure of merit approaching $120^\circ/\text{dB}$ at 40 K.³³ At room temperature, using Au electrodes and 400 nm thick $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$ films devices have demonstrated $\approx 70^\circ/\text{dB}$.³⁴ These planar phase shifters are fairly compact, low loss, easy to fabricate, and can provide 360° of phase shift with bias voltages under 350 V. Such devices can enhance conventional (direct radiating) phased array performance or enable a new type of reflectarray antenna.^{35,36} Only one control line is required per phase shifter, thereby simplifying array assembly. A variation is a hybrid X-band phase shifter consisting of four cascaded coupled microstrip lines, patterned over 400 nm thick laser-ablated $\text{Ba}_{0.50}\text{Sr}_{0.50}\text{TiO}_3$ films, followed by a switch.³⁷ The ferroelectric section provides (nominally) 180 degrees of analog phase shift. Basically, as a bias from 0 to 350 V is applied across the coupled line electrodes, the relative dielectric constant of the film tunes from about 2000 to 800, thereby modifying the propagation constant. The ferroelectric films are, of course, excellent dielectrics and the current draw is negligible so there is virtually no power consumption. Switching speed for these devices is limited by the external power supply. This is analogous to MESFET switches, wherein there is no drain bias. The variable resistance of a FET switch is a function of the population of majority carriers, as opposed to minority carriers in PIN diodes. (For example, in FET switches, speed is not limited by minority carrier lifetime, but rather the gate control circuitry). The beam lead GaAs diode switch is appended to the last coupled microstrip section and toggles between an open and virtual short circuit, realized with a quarter-wave radial stub. This results in a “digital” transition between a reflection coefficient with magnitude near unity and phase of ≈ 0 degrees and ≈ 180 degrees, respectively. Thus, a full 2π phase shift is possible. The average loss at X-band was 3.2 dB with a 10% bandwidth. The device is pictured in Figure 21-8. Note that the unmatched beam-lead diode contributed 0.5 to 0.75 dB to the overall insertion loss. In principle, this can be improved by “resonating-out” the diode capacitance.

Theory of Coupled-Line Type

A sketch of the cross-section of a coupled-line (multi-dielectric-layer) ferroelectric phase shifter is shown in Figure 21-9. Y_1 and Y_2 represent the admittance looking in the positive and negative y direction, respectively, from the charge plane. The thickness of the ferroelectric layer is h_1 while the host substrate has thickness h_2 .

By concentrating the fields in the odd mode, the phase shift per unit length is maximized, and by using the material in thin film form, the effects of high loss tangent are reduced.

The amount of phase shift can be increased by cascading coupled line sections. Though methods for calculating the propagation parameters of coupled transmission lines are well known, coupled lines on stratified substrates are difficult to analyze. And the high permittivity of the ferroelectric layer causes long computation time by full-wave electromagnetic

FIGURE 21-8 Hybrid X-band ferroelectric/semiconductor phase shifter on 0.5 mm thick lanthanum aluminate. The device measures $\approx 1 \times 1$ cm.

simulators because the geometry must be fractured into many thousands of cells. The multilayer structure has been analyzed using a computationally efficient variational method for calculating the complex propagation constant and characteristic impedance.³⁸ Space limitation prevents a full description of that work here. However, the method is quite general and can be used for multiple layers of various dielectrics or other types of transmission lines. For example, a multilayer microstrip can be analyzed by allowing the strip spacing (s) to become much greater than the effective substrate thickness (h) or strip width (w). Minimum loss occurs when current flows through one line and returns through the other (odd-mode),

FIGURE 21-9 Cross-section of the coupled microstripline phase shifter, showing the odd-mode electric field configuration

FIGURE 21-10 Coupled line modes: microstrip mode (left), $s \gg h, w$; odd-mode (middle); even-mode (right)

obviating the need for the ground plane. Maximum loss occurs when equal currents flow through the two lines and return through the ground plane (even-mode). Three basic modes are illustrated in Figure 21-10.

Note that the ferroelectric layer thickness is crucial to performance. In principle, the phase shift for a $2\text{ }\mu\text{m}$ thick film is 2.2 times greater than that of a $0.5\text{ }\mu\text{m}$ film. However maintaining the crystalline quality of the pulse laser ablated $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$ films past a thickness of $0.5\text{ }\mu\text{m}$ or so has proven to be difficult. Experiments have shown that the insertion phase shift is roughly proportional to $h_1^{0.67}$. In the case of cascaded coupled lines, increasing phase shift occurs at the expense of bandwidth since the structure resembles a multipole filter. Changing the dielectric constant of the ferroelectric film to change its insertion phase also modifies the pass band characteristic. Operation near band edges is to be avoided since that represents distorted transmission which degrades bit-error-rate performance. The device discussed in the previous section “Coupled Microstripline” helps alleviate this problem. The impedance matrix of the cascade network can be derived by traditional coupled line theory, using the superposition of even and odd mode excitation. Then an equivalent S-parameter model can be extracted and used to predict the pass-band characteristics of the phase shifter. A key advantage of this technology is the relatively large feature size. Active devices at the frequencies of interest here would necessitate submicron gate length GaAs FETs. The finest feature size associated with the coupled-line phase shifters is the electrode separation, typically $\approx 10\text{ }\mu\text{m}$. Whereas the GaAs FET performance is largely dictated by transconductance, and hence, carrier transit time across the gate region, the coupled-line phase shifters are static devices. The electrode gap separation determines the degree of electromagnetic coupling and the dc potential required to tune the film.

21.4 MEMS

Micro-electro-mechanical systems (MEMS) can essentially be used to replace PIN diode or FET switches in conventional phase shifters. A typical switch consists of a metal membrane bridge suspended several microns above a lower metal contact. Electrostatic attraction between the flexible membrane and lower contact is used to toggle the switch. A very thin dielectric coating (for example, Si_3N_4) may be used on the lower contact to eliminate a dc path and reduce “stiction,” or a tendency to latch (also known as Van der Waals forces). Larger bridge heights (gaps) reduce parasitic capacitance, but increase pull-down voltage and may contribute to more fatigue. Typical actuation voltages are between 20 and 100 V. An interesting advantage of MEMS switches is that they do not depend on the characteristics of the substrate. Hence, they may be fabricated on any material that is compatible with standard IC processing. A photograph of one type of MEMS switch is shown in Figure 21-11. Optimizing the switching Q amounts to minimizing the parasitic capacitance of the bridge in the off state (bridge up), and maximizing capacitance in the on state (bridge down). When the cantilever is down, the parallel plate capacitance between the metal membrane and the bottom electrode, C_{on} , is large and the switch behaves as a short circuit. Typical ratios of $C_{\text{on}}/C_{\text{off}}$ are ≈ 100 .

FIGURE 21-11 RF MEMS capacitive switch. MEMS devices incorporating capacitive\inductive sections allow the switch to be designed for minimum loss and maximum isolation over a wide frequency range (after M. Scardelletti⁴³ © IEEE 2002).

A number of distributed MEMS transmission line phase shifters have been developed.³⁹ An insertion loss of 4 dB at 60 GHz (for a full 360° phase shift) and 257°/dB at 50 GHz has been reported.⁴⁰⁻⁴¹ These excellent results have been obtained from MEMS bridge capacitors placed periodically along a coplanar waveguide (CPW) transmission line. The theory of such “slow-wave” circuits is discussed in the next section. Activating the MEMS increases the capacitive loading, thereby controlling the insertion phase. A mechanical analysis of operation was provided⁴² and the bridge spring constant was given as

$$k \approx 32Et^3w/(S+2W)^3 + 8\sigma(1-\nu)tw/(S+2W)N/m \quad (21-12)$$

where E is Young’s modulus of the bridge material, t is the bridge thickness, w is the bridge width, S is the CPW center conductor width, W is the CPW center conductor-to-coplanar ground spacing, σ is the internal residual stress of the bridge, and ν is Poisson’s ratio. The pull-down voltage V_p is given as

$$V_p = [8\text{ kg}_0^3/(27\epsilon_0 S w)]^{1/2} V \quad (21-13)$$

where ϵ_0 is the free-space permittivity and g_0 is the zero-bias bridge height.

One issue with MEMS phase shifters is that packaging is perhaps more critical than with alternative technologies. Hydrocarbon contamination may compromise MEMS reliability so hermetic seals and careful processing are required. A summary of performance and implications for phased arrays are presented in the reference section.⁴⁴⁻⁴⁵

21.5 SLOW-WAVE

Periodically loaded transmission lines are used to realize band-pass, slow-wave circuits such that $v_p \ll c$. By using tunable loads or varactors, broad-band phase shifters can be designed.

One-Dimensional Periodic Structures

Consider a cascade of short sections of lossless transmission line shunted by a voltage variable capacitance C' , so as to form the infinite periodic structure illustrated in Figure 21-12. Each distributed transmission line section is modeled by an LC circuit and each unit cell consists of L , C , and C' . Let the separation of each unit cell be designated as s . Such periodic structures exhibit slow-wave behavior ($v_p \ll c$) and band-pass characteristics, like filters.

FIGURE 21-12 A chain of LCC' circuits representing an infinite, periodically loaded transmission line resulting in slow-wave propagation

The phenomenon is analogous to acoustic wave propagation in crystal structures. These types of circuits are often referred to as synthetic line, slow-wave, or distributed transmission line phase shifters.

A wave traveling through this periodic structure will only experience a phase shift from unit cell to unit cell, such that V_n is delayed relative to V_{n-1} as

$$V_n = V_{n-1} e^{-j\theta_s} \quad (21-14)$$

In general, θ_s could be complex to account for attenuation as well as phase shift. Summing currents leaving node n

$$0 = V_n(j\omega C + j\omega C') + (V_n - V_{n-1})(-j/(\omega L)) + (V_n - V_{n+1})(-j/(\omega L)) \quad (21-15)$$

Substituting Eq. 12 into Eq. 13 we arrive at

$$\cos(\theta_s) = \frac{1}{2}(2 - \omega^2 L(C + C')) \quad (21-16)$$

Requiring θ_s to be real to represent a propagating mode, letting $\cos(\theta_s) = \pm 1$, we find the structure of Figure 21-12 has a zero lower frequency cutoff ω_L (obvious by inspection) and an upper cutoff frequency ω_H corresponding to

$$\omega_H = 2/(L(C + C'))^{1/2} \quad (21-17)$$

Since $\theta_s = \beta s$, the insertion phase shift can be approximated knowing the extremes of the tuning range of C' and the number of cascaded sections. Slow wave phase shifters are, in principle, time delay devices (in other words, phase shift is proportional to frequency).

Ferroelectric Varactor

One type of slow wave phase shifter, based on ferroelectric “varactors” is shown in Figure 21-13. Coupled lines, as described in the previous section called “Theory of Coupled-Line Type,” are attached transversely to the propagation direction in a microstrip configuration.⁴⁶ A unit cell consists of two microstrip sections, with an intervening orthogonal coupled microstrip line terminated in a virtual open circuit. The open circuit is realized by cascading a nominally quarter-wave high-impedance microstrip line, having impedance Z_p , with a radial stub. The stub provides a very good approximation to a short circuit at its vertex, over almost an octave bandwidth, and the input impedance (Z_{in}) to the combination is approximately $35Z_p/\alpha$, where α (dB/ λ) is the attenuation of the Z_p line. Note that there is an optimal choice for Z_p , since as Z_p increases to maximize Z_{in} , α also increases due to conductor loss.

FIGURE 21-13 Modeled impedance variation of a 19-cell slow wave circuit from 18 to 20 GHz as the ferroelectric film dielectric constant varies from 2000 to 800 (left). The actual circuit (right) had a 0.6 mm cell size with 200 μm long coupled-line varactors.

For the reactances chosen and shown, the modeled dissipative loss was about 0.125 dB/unit cell. There is a trade-off between loss and phase shift. For a median varactor reactance of $-j500$, the calculated loss per unit cell is 0.003 dB, but the phase shift is also $\ll 1^\circ/\text{cell}$ and appears impractical. For a reactance of $-j5$, the insertion loss is about 8.6 dB/cell and is also impractical. For the K-band circuit shown, the varactors theoretically tuned from 0.45 pF (zero bias) to 0.25 pF (maximum bias), and 16 unit cells should have provided 360° of phase shift at 20 GHz. These results could be obtained using the techniques described in the subsection entitled “Coupled Microstripline.” The measured phase shift of the actual 19 cell structure was about 250° with an average loss of about 7.5 dB.

Excellent results have been obtained from slow wave circuits using parallel-plate ferroelectric varactors.^{47–49} The circuits operating principles are basically as described in Section 21.5. The device consists of a high impedance transmission line on sapphire, periodically loaded with $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$ capacitors spaced by distance s . Recently, $\approx 360^\circ$ phase shifters at K- and Ka-band exhibited an average loss of about 5 and 6 dB, respectively.⁵⁰ One advantage of the parallel plate approach is that conventional tuning voltages can be used (for example, ≈ 10 V as opposed to >100 V for coplanar structures). Another advantage is that circuits can be fabricated on convenient substrates like Si instead of exotic, high epsilon substrates like LaAlO_3 . Propagation in semiconductor substrates has also been discussed.⁵¹ The circuits are also extremely compact. A Ku-band version measuring 1×0.8 mm was reported.⁵⁰

Ferroelectric deposition methods (for example, pulse laser, sputtering, and so on) require an oxidizing atmosphere around 700°C to achieve high quality crystalline films. Hence, electrodes for parallel plate varactors, as opposed to the coplanar or interdigital structures described previously, must be impervious to high temperature oxidizing atmospheres. Low dielectric constant oxides at the electrode interface can drop most of the electric field and substantially reduce tuning. Pt is a popular electrode material choice.

21.6 FERRITE

The fundamental source of a material’s magnetic properties is the magnetic dipole moment associated with what is visualized as an electron spinning about its axis. In non-magnetic materials, the number of electrons with up spins and down spins is equal, so the net magnetic moment is negligible. In a magnetic material, one variety dominates and can be aligned by an external DC magnetic bias field H to generate a large magnetic moment, as long as thermal fluctuations aren’t too strong. The spin magnetic moment vector precesses about

the H -field vector at an angular frequency $\omega_m = 2\pi f_m$. Precession sense (i.e., polarization) depends on the direction of H . The precession frequency is proportional to H such that $f_m = \gamma H$, where $\gamma = 2.8 \text{ MHz/Oe}$ is the gyromagnetic constant. The propagation constant (β) in a ferromagnetic medium is

$$\beta \approx (2\pi\sqrt{\epsilon\mu'})/\lambda \quad (21-18)$$

where μ' is the real part of the permeability and ϵ is the dielectric constant of the ferrite. When the frequency f of a microwave magnetic field equals f_m , ferrimagnetic resonance occurs. This is the underlying cause for opposite circularly polarized waves experiencing different permeabilities, μ'_+ and μ'_- . In the absence of any loss mechanism, the material's susceptibility would become infinite at the gyromagnetic resonance frequency. The permeability can be tuned by changing M , which is the magnetization or magnetic moment. As the strength of the magnetic bias field increases, M will reach an upper limit called the saturation magnetization, denoted as M_s . Ferrite materials tend to have high loss below saturation at microwave frequencies. The choice of ferrite for a particular application is determined by selecting $\gamma 4\pi M_s$ sufficiently below the operating frequency f . When f_m is small compared to f , there is a significant difference between μ'_+ and μ'_- for the two polarization senses. (Recall that a linearly polarized wave can be disassociated into two counter-rotating circularly polarized components). With this condition, it can be shown that⁵²

$$\mu'_{\pm} = 1 \mp \gamma 4\pi M/f \quad (21-19)$$

and the corresponding phase shift is

$$\Delta\phi = 2\pi\sqrt{\epsilon} [(\mu'_+)^{1/2} - (\mu'_-)^{1/2}]L/\lambda \quad (21-20)$$

where L is the length of the ferrite section. In practice, the phase shift is implemented by reversing the direction of the magnetization vector.

As was alluded to in the introduction, ferrite phase shifters have tended to dominate the phased array landscape. The basic, nonreciprocal, latching phase shifter consists of a toroidal ferrite core in a section of waveguide. A drive wire passes through its center, which is used to magnetize the material. At this point it becomes latched at one of two remanent states, depending on the polarity of the bias. The amount of differential phase shift between the two states is determined by the toroid length. Another common device is the reciprocal, non-latching Reggia-Spencer phase shifter. A ferromagnetic bar is located axially in a section of waveguide, which is wound by a solenoid. The solenoid produces a longitudinal magnetic field that changes the permeability of the bar material. The reader is referred to the previous edition of this book and the references therein for complete descriptions. The performance of twin-toroid, dual-mode, and rotary-field ferrite phase shifters has been discussed elsewhere.⁵³

Microstrip Type

Our interest here will be a brief introduction to microstrip-type ferrite phase shifters. Planar microstrip geometries promise an economical and small-sized replacement for waveguide phase shifters. For example, a small analog X-band stripline on a ferrite slab yielded a figure-of-merit of 300°/dB with a 30 mW average drive power.⁵⁴ A renewed interest in this type of device was spurred on by the advancement of high-temperature superconductors, which are briefly discussed in the next section. The key advantage of superconducting transmission lines is the very low surface resistance compared to metallic conductors.

FIGURE 21-14 Geometry for a superconducting microstrip meander line phase shifter inverted and in close proximity to a tunable ferrite substrate. The device is about 1.3 cm long (after G. F. Dionne et al.⁵² © Lincoln Laboratory, MIT 1996).

Low-loss microstrip ferrite phase shifters were demonstrated by combining the superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with polycrystalline yttrium iron garnet $\text{Y}_3\text{Fe}_5\text{O}_{12}$. The design confined the magnetic flux within the ferrite to avoid undesirable flux penetration into the superconductor, yet allowed gyromagnetic interaction with the microwave signal.⁵⁵⁻⁵⁶ A prototype phase shifter using a $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ microstrip meander line deposited on a LaAlO_3 substrate is shown in Figure 21-14.

A differential phase shift in excess of 200 degrees with an insertion loss generally below 2 dB from 6 to 12 GHz was reported.⁵² Besides the insertion loss advantage of the superconducting line, the $4\pi M_s$ values can increase by more than a factor of two when the material is cooled from 300 K to 77 K.

21.7 SUPERCONDUCTING APPLICATIONS

While conventional or low temperature superconductor based phase shifters have been developed to some extent,⁵⁷⁻⁵⁸ the discovery of so-called “high-temperature” ceramic superconductors in 1986⁵⁹ ushered in a new class of microwave components. High temperature superconducting (HTS) phase shifters are a subset of that class. The main attraction was dramatically reduced surface resistance compared to metallic conductors. The three primary HTS materials are $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, BiCaSrCuO_x , and $\text{Tl}_2\text{Ba}_2\text{Ca}_2\text{O}_x$ with respective transition temperatures (T_c) of 95 K, 110 K, and 122 K. Surface resistance (R_s) of these superconducting films at 77 K is on the order of $100 \mu\Omega$ at 10 GHz, compared to about $10 \text{ m}\Omega$ for copper.

The surface impedance of a superconductor is derived using a two-fluid model, which maintains that the current is composed of both superconducting (paired) and normal electrons. The proportion varies such that at $T = 0$, all carriers are superconducting and at $T = T_c$, all carriers are normal. The two-fluid model predicts that the surface resistance of a superconductor is proportional to f^2 , as opposed to $f^{1/2}$ for a metallic conductor.⁶⁰ The strong dependence of R_s on frequency is a consequence of reactive voltage, associated with the oscillating supercurrent interacting with unpaired (normal) electrons to induce loss. The corresponding (inductive) surface reactance is $\omega\mu\lambda_L$, where λ_L is the London penetration depth. λ_L has a minimum value at $T = 0$ and diverges as T approaches T_c . The abrupt change in resistance and kinetic inductance ($\mu\lambda_L$) near T_c presents opportunities for novel detectors (for example, transition edge bolometers) and switching mechanisms.

Reflective switches can be based on driving a narrow superconducting bridge into the normal state by locally exceeding the superconductor’s critical temperature.⁶¹ Alternatively,

a magnetic field on the order of 100 G was used to cause a small bar of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ to transition from the superconducting to normal state.⁶² The effects of optical illumination have also been investigated.⁶²⁻⁶³

A novel phase shifter based on a HTS distributed Josephson inductance transmission line was reported.⁶⁴ Superconducting quantum interference devices (SQUIDs), consisting of a superconducting inductor shorted by a Josephson junction, were distributed along a length of superconducting transmission line. Each SQUID can be modeled as a variable inductor, which is tuned by applying a magnetic field. The circuit constitutes a dual of the structure discussed in Section 21.5. Slow-wave propagation in superconducting transmission lines has also been studied. For example, the dramatic increase in λ_L near T_c causes a large reduction in v_p if the film is very thin.⁶⁵

We conclude this section noting that the field of cryogenic electronics is growing and may be further stimulated by recent advances in compact, reliable, mechanical refrigerators. While a few esoteric systems have been created for space-based astrophysics, ultra-sensitive receivers, and medical diagnostics, there may also be niche applications in communications markets. Cryogenically cooled receivers for cellular phone towers are a good example. The enhanced sensitivity allows for increased cell-size. It is easy to speculate that applications for cryogenically cooled agile antennas, and hence phase shifters, may also eventually exist. Digital beam-forming systems based on Josephson technology are also being contemplated.

21.8 EFFECT OF PHASE SHIFTER BEHAVIOR ON PHASED ARRAY BIT ERROR RATE

Phase shifters' phase errors can cause some signal distortion, and phase transients can cause beam pattern degradation during direction switching. Signal models have been established for both static and transient cases. Moreover, modulo 2π effects cause intersymbol interference (ISI). This section is based on the work reported in this area.⁶⁶

Modulo 2π Effects

The composite far-field signal formed by a phased array is the summation of individual contributions from each elemental radiator. Radiation path lengths to the far-field observation point are different for each elemental radiator on the array surface. To form a cophasal beam, modulo- 2π compensation is provided by the phase shifters. Integer-multiples of 2π are generally not provided, and for an electrically large array, this leads to inter-symbol interference (ISI) in phase-shift keyed modulation formats. The ISI is formed because different delays from each signal component destructively interfere, as illustrated in Figure 21-15, for Binary Phase Shift Keyed waveforms. ISI results in composite (total) signal amplitude loss at the symbol boundary.

As an example, for the reflectarray³⁵⁻³⁶ operating at $f = 26.5$ GHz with a bit rate of 1.325 Gbps, the BER degradation due to ISI is proportional to the symbol rate and the loss ranges are from about 1 dB to around 2 dB in E_b/N_0 , depending on original E_b/N_0 , for BPSK, QPSK, 8PSK, and 16QAM.

Phase Errors

Each phase shifter assigned to each element is designed to shift the signal phase by an amount determined by the steering angles of the antenna. In practice, however, there are errors in the phase shifters. Assume that the phase errors are uniformly distributed in

FIGURE 21-15 Formation of ISI due to different delays in signal components. The carrier period is designated T_c . Heavy vertical lines are symbol boundaries (after F. Xiong and R. Romanofsky⁶⁷ © IEEE 2005).

$[-\Delta\varphi_{\max}, \Delta\varphi_{\max}]$. It was shown in that the averaged effect of phase error is to introduce an amplitude loss of

$$L_{\Delta\varphi} = \frac{\sin \Delta\varphi_{\max}}{\Delta\varphi_{\max}} \quad \text{or} \quad L_{\Delta\varphi} (\text{dB}) = 20 \log \left| \frac{\sin \Delta\varphi_{\max}}{\Delta\varphi_{\max}} \right| \quad (21-21)$$

and there is no net phase shift of the composite signal due to the phase errors. For a maximum phase error of $\pi/8$, the loss is only 0.224 dB. It can be seen that the phase error loss is a sinc function of $\Delta\varphi_{\max}$ and it can be shown that the maximum phase error must be less than 47° to limit the loss within 1 dB.

The real composite signal will have not only amplitude loss, but possibly also a small net phase error. The small net phase error could have a degrading impact on the BER performance of the high-order PSK schemes and QAM schemes, since the phase differences between constellation points are very small.

Effect of Finite Response Time on Beam Evolution

Different types of phase shifters will have different transient response times. Table 21-2 in the next section provides a qualitative assessment. When the array beam is switched from one direction to another, the finite response time of the phase shifters causes the beam pattern to evolve. This effect is in addition to the ISI and phase error described earlier. The problem was analyzed by incorporating the phase transient in the array factor. For the 925 element array investigated there, which assumed a quite long 0.3 ms average phase shifter response time, the directivity degraded by as much as 1.9 dB during position updates.

Experimental results were reported⁶⁸⁻⁶⁹ that would, of course, include all the effects described herein. Clearly, electrically large phased arrays communicating wide-band signals with high order modulation formats must be designed to compensate for these effects. A set of BPSK BER curves for various conditions is shown in Figure 21-16 (transient effect excluded). The term “without antenna” means that the antenna is ideal—no phase errors and no ISI.

FIGURE 21-16 BER curves for BPSK (after F. Xiong and R. Romanofsky⁶⁷ © IEEE 2005)

TABLE 21-2 Comparison of Phase Shifter Technologies

Type Feature	Ferroelectric	Semiconductor/ MMIC	Ferrite	MEMS
Cost	Low	Expensive	Very expensive	Low
Reliability	Good after 10^6 0-40 V/ μm bias cycles (more tests required)	Very good (if properly packaged)	Excellent	Good after several billion cycles (more tests required)
Power handling	Good, >1W	Very good, tens of watts	Very high (kW)	Low Power, <50 mW for high reliability
Switching speed	Intrinsically fast ($\approx\text{ns}$), controller limited if high voltage	Fast at low power ($<10^{-9}\text{s}$)	Slow (inductance) 10 to 100 μs	Slow (mechanical) 10 to 100 μs
Radiation tolerance	Excellent	Poor (good if radiation hardened)	Excellent	Excellent (mechanical; no solid state junctions involved)
DC power consumption	Low ($<<1\text{ }\mu\text{A}$ current) μW	Low ($<10\text{ mW}$ for diodes; negligible for FETs)	High (large current) $\approx 10\text{ W}$ ($\approx 1\text{ W}$ if latching)	negligible
RF loss	$\sim 5\text{ dB}/36^\circ$ @ K-band	$\sim 2\text{ dB/bit}$ @ Ka-band = 8 dB	$<1\text{ dB}$ / 360° @ X-band	$\sim 2.3\text{ dB}/337.5^\circ$ @ Ka-band
Size	Very small if parallel plate varactor (mm^2)	Small ($\approx 10\text{ mm}^2$ at Ka-band)	Large (wave-guide, bias coil)	Small (comparable to MMIC)
Linearity	IMD intersect +60 dBm	IMD intersect +35 to +40 dBm		IMD intersect +80 dBm

21.9 SUMMARY

This chapter reviewed basic phase shifter theory and described some modern phase shifter devices. Key developments of the past decade or so include devices based on GaAs MMIC, MEMS, and thin ferroelectric films. Applications of superconductivity were also briefly described. Some interesting effects are expected to manifest themselves as the ratio of signaling bandwidth to carrier frequency decreases, especially with regard to electrically large phased arrays. An important aspect of phase shifter performance is power handling capability. The reader is referred to the reference section⁷⁰⁻⁷³ for information on this topic. A summary of phase shifter characteristics is presented in Table 21-2.

22.4 PATTERN SYNTHESIS FOR CYLINDRICAL SECTOR ARRAYS	22-20

22.1 INTRODUCTION

A number of applications require antenna arrays conforming to a nonplanar surface. Primary among these are requirements for scanning antennas on aircraft or missiles, where aerodynamic drag is reduced for a conformal flush-mounted geometry, and for arrays that conform to surfaces that provide some coverage advantage, for example, to a hemispherical surface for hemispherical-pattern coverage or to a cylinder for 360° coverage in the azimuth plane.

Conformal arrays can be grouped into two broad categories that have very different design goals and that present significantly different technological challenges. Arrays in the first category are small with respect to the radius of curvature of the conformed body, as depicted in Figure 22-1a. These proportions are representative of flush-mounted and low-profile aircraft arrays at superhigh-frequencies (SHFs) and above. These are relatively flat and behave nearly like planar arrays. The technological challenges in this case are to design an array to scan over very wide angles (for example, zenith to horizon) or to make the array so thin that it can conform to the outer surface of the aircraft without requiring large holes in the fuselage.

The second category of conformal arrays, depicted in Figure 22-1b, is the type more commonly regarded as conformal since the array is comparable or large with respect to the radius of curvature of the mounting body. Such arrays include cylindrical arrays developed to provide radiation from spinning missiles and for 360° coverage of ground-based radars. Conical and spherical arrays have also been developed for ground-based radars. Conical and spherical arrays have also been developed for ground, airborne, and missile applications.

Among the special features that make it difficult to design arrays that are large or highly curved in this sense, the following are usually listed:^{1,2} (1) Array elements point in different directions, so it is often necessary to switch off those elements that radiate primarily away from the desired direction of radiation. (2) Conformal-array synthesis is very difficult because you cannot factor an element pattern out of the total radiation pattern. (3) Mutual coupling can be severe and difficult to analyze because of the extreme asymmetry of structures like cones and because of multiple coupling paths between elements (for example, the clockwise and counterclockwise paths between elements on a cylinder). Another phenomenon related to mutual coupling is the evidence of ripples on the element patterns of cylindrical arrays. (4) Cross-polarization effects arise because of the different pointing directions for elements on

FIGURE 22-1 Conformal-array apertures: (a) aperture dimensions much less than local radius of curvature and (b) aperture dimensions comparable with local radius of curvature

curved surfaces, which cause the polarization vector projections to be nonaligned. (5) Even for a cylindrical array there is a need to use different collimating phase shifts in the azimuth plane for an array scanned in elevation because steering in azimuth and elevation planes is not separate.

22.2 FUNDAMENTAL PRINCIPLES

Properties of Isolated Elements on Finite Planes and Cylinders

Radiating elements behave differently according to the structure on which they are mounted. Examples of elementary slot antennas radiating from circular cylinders show significant pattern changes at angles near or below the horizon for a slot located at the top of the cylinder.

Figure 22-2 shows the radiated power pattern in the upper hemisphere ($\theta \leq 90^\circ$) for an infinitesimal slot in a cylinder of radius a . Using the results of Pathak and Kouyoumjian,³ you can express the radiation pattern of elementary slots on cylinders in terms of three distinct regions, depending upon whether the point of observation is in the upper hemisphere (called the *illuminated region*), in the lower hemisphere (called the *shadow region*), or in the vicinity of the horizon (called the *transition region*). The angular extent of the transition region is of the order of $(k_0 a)^{-1/3}$ on each side of the shadow boundary. Figure 22-2 illustrates that within the illuminated region the circumferentially polarized radiation is nearly constant for an infinitesimal element but that the axially polarized radiation has a $\cos \theta$ element pattern. Moreover, within the transition region these patterns are modified so that the circumferentially polarized component drops to a value of about 0.7 in field strength, or -3.2 dB as compared with its value of zenith, while for axial polarization the horizon radiation is not zero but approximately

$$0.4 \left(\frac{2}{k_0 a} \right)^{1/3}$$

Thus for a thin slot with circumferential polarization, the horizon gain is independent of the size of the cylinder, but for an axially polarized slot, the horizon gain varies directly as a function of $(k_0 a)^{-1/3}$. For cylinders of radius approaching 50λ , the horizontally polarized power at the horizon is thus approximately 23 dB below zenith gain.

FIGURE 22-2 Approximate pattern of slot on cylinder of radius a

Pattern Coverage Limitations for Conformal Arrays

In addition to the diffraction effects observed in the preceding section, purely geometrical effects play a major part in determining the pattern characteristics of conformal arrays. Figure 22-3 shows a conical array of slots from several angles and illustrates the polarization distortion that occurs for an array near the tip of a cone. This figure, due to Kummer,¹ shows three views of a conical array with radiators located along the generatrices and oriented to give linear polarization in the axial direction. Clearly this array radiates a different polarization for each chosen angle of radiation.

A second issue raised by the picture of the conical array is that all of the elements have different element patterns because each is a different distance from the tip and each is at a different azimuth angle. Even if the elements near the tip are left out (since they are few and so have relatively little gain), only a small number of radiators have element patterns that point in the required direction. It is therefore usually necessary to devise a sophisticated network to switch an illuminated sector to the proper location on the conformal array for efficient radiation. Such networks now exist for cylindrical arrays, but the problem is more severe for cones, spheres, and more general surfaces. In addition, because of the polarization rotation, it may be necessary to align the element polarization in order to radiate efficiently. Finally, it is difficult to maintain good monopulse nulls for directions in which there is not even symmetry.

Since the elements may point in different directions, there is a size limit for an array that can be wrapped around a conformal body without sacrificing efficiency. Figure 22-4a shows the radiation pattern of several cylindrical arrays computed as a function of the angle subtended by the array. As pointed out by Hessel,⁴ for an array of $k_0 a = 86$, with 0.65λ separation between elements, doubling the number of excited elements in the array (from a 60° to a 120° arc) increases the array gain by only about 1 dB because the edge elements do not radiate efficiently toward the beam peak. The large sidelobes near $\phi = 100^\circ$ are associated with grating lobes of the elements grouped at the array ends, which are necessarily scanned to very wide angles.

Closer element spacing can relieve the grating-lobe problem and can broaden the element patterns, as will be described in Section 22.3, but Figure 22-4b shows that the gain restrictions are fundamental limitations. This figure shows the gain of a cylindrical array

FIGURE 22-3 Conical array: (a) view from axial direction, (b) side view, and (c) side view rotated 90° from b (after Kummer¹ © IEEE 1974)

FIGURE 22-4 Radiation characteristics of arc arrays: (a) maximum-gain E -plane patterns for arc array of $k_0 a = 86$, $b/\lambda = 0.65$ (after Hessel⁴ © Artech House 1972) and (b) normalized projected area weighted by element patterns

with assumed power patterns $\cos^1 \theta$, $\cos^2 \theta$, and $\cos^3 \theta$. It is also assumed that the element spacing approaches zero (the continuous aperture case) and the gain, normalized to the gain of the projected area of the cylindrical section, is the integral of the \cos^n functions up to the maximum θ value. This is a good approximation for radii greater than about 5 wavelengths, and for element spacing up to a half wavelength. Additionally, the circular arc arrays require more elements than a planar array with the same projected area, so if the normalized gain were normalized to the number of elements to fill the sector, then the comparison with a planar array is made worse. The circular sector with included angle $2\theta_0$ requires about $\theta_0/\sin(2\theta_0)$ more elements than the projected aperture [a factor of 1.1 (0.41 dB)] for a 90° sector, and 1.6 (2.04 dB) for a 180° sector. These two limitations show that there is little advantage to exciting much more than a 90° section of the cylinder.

A second fundamental result is obtainable from the same very simplified analysis. For a four-faced square array with perimeter equal to the circular-array circumference, the average gain over a 90° scan sector, normalized again to the cylinder projected area, is approximately -1.5 dB for a $\cos \theta$ element pattern, and -1.9 dB for the $\cos \theta^2$ element pattern. Figure 22-4b shows that these are essentially the same as the gain of a 90° arc circular array with the same element pattern. A similar result is quoted by Hessel.⁴

The preceding results are derived for uniformly illuminated arrays. When arrays have severe illumination tapers, as for example in low sidelobe arrays, it is possible to occupy larger circular arcs without reduced efficiency because of the low edge illumination.

Technology of Conformal Arrays

The dramatic illustration chosen by Kummer¹ (see Figure 22-3) points out the difficulty of synthesis on conical and more generalized surfaces that arises because such structures project differently into different angular regions. Nevertheless, cylinders, cones, and spheres are important surfaces for conformal array development because of their obvious application to missile and certain hemispheric scanning structures.

The technology of conformal arrays is very different from that of planar arrays. Often conformal arrays must be flush mounted or low profile, and structurally integrated with the platform with little intrusion. Thus, even for arrays that do not wrap around the body of the vehicle significantly, there is still a basic difference in the technology. The second major distinction is that the excitation of an array that is large with respect to the local radius of curvature needs to be commutated around the body, and this can be a significant burden. Commutators devised for cylindrical arrays are described in Section 22.3. Analog commutating networks for general conformal arrays require complex switching trees that are costly, lossy, and hard to implement, and that often require both amplitude and phase control.

One special type of space-fed commutating network has been developed for cylinders and spheres. The Dome antenna,^{5,6} shown in Figure 22-5 in its spherical version, uses the vertical projection of a spherical dome to achieve increased gain at low angles of elevation. The dome is a passive spherical lens made up of fixed phase shifters and fed by a conventional planar

(a)

(b)

FIGURE 22-5 Hemispherical dome array: (a) dome array and (b) dome-antenna concept (Courtesy of Sperry Corporation)

phased array that steers an illuminated spot to various portions of the lens. Fixed phase shifters in the lens are computed so as to convert the array scan direction θ into a factor K times that angle, and so as to obtain scan in excess of the planar array scan angle. The array phase shifter settings are determined to form the nonlinear phase progression required to scan the searchlight-type beam to various spots on the lens. Although the radiated beamwidth varies with scan angle, the dome can achieve scanning over sectors larger than a hemisphere and has achieved scan to $\pm 120^\circ$ from zenith. Steyskal et al⁶ give equations for the gain limits of a given circular cylindrical dome based upon allowable scan angles for the feed array and show that the ratio of the average gain to the broadside feed array gain is bounded by a parameter that depends upon the feed array scan limit.

In the general case where there is not enough volume to use a space feed, other means of commutating the illumination are needed to scan a large conformal array. There are several new technologies that can accomplish this. The first is the technology of solid state T/R modules to control the aperture illumination. In this case, you can control the distribution using resistive attenuators and linear amplifiers or by using amplifiers with variable gain to move the amplitude distribution around the array structure and so achieve high quality patterns, even for highly curved arrays.

Figure 22-6 shows⁷ a faceted array of dual polarized dipole elements conformal to a sphere and using six elements per facet. The array is intended for satellite communication from mobile units and has integrated transmit-receive electronics, using GaAs MMIC circuits.

FIGURE 22-6 Faceted spherical array (Courtesy of Roke Manor Research Ltd., Roke Manor, UK)

The second approach is to implement full digital beamforming across the array. This approach, which can be used for transmit and receive, has thus far been implemented in a number of receive arrays that transmit using conventional analog methods. In the receiving array, the received signals are amplified, possibly down converted, and then digitized. Amplitude and phase weights for commutation are applied to the digitized signals. Though presently expensive, this technology is seen as the ultimate in performance. Three significant examples were presented at the 1996 Phased Array Symposium showing the application of digital beamforming to conformal receive arrays. The first⁸ was an array of 570 *X*-band active T/R modules that excite an array conformal to an elliptical cylinder. Measured low sidelobe receive patterns were below -38 dB, and additional measured patterns demonstrated the accurate synthesis of flat-topped sector patterns, cosecant squared patterns, and several patterns with anti-clutter nulls. In each case the patterns were synthesized using measured element patterns. A second example⁹ used an array of 576 T/R modules conformal to a doubly curved surface. Sample patterns confirmed about the same level of sidelobes as the previous study, and the ability to reconfigure the aperture to produce a variety of shaped patterns. A hemispherical array¹⁰ using the same T/R modules formed sidelobes at the -40 -dB level.

Another example of the power of these digital techniques for conformal arrays is the work of Steyskal,¹¹ who demonstrated a technique for forming frequency independent patterns with a circular cylindrical array. The symmetry property of a circular array of N elements leads to expansion of the fields in terms of orthogonal "phase modes,"¹² of signals that advance in phase with interelement phase $2\pi n/N$ for $1 \leq n \leq N$. This orthogonality corresponds to the beam port relations of an orthogonal beam (Butler) matrix, or a digital FFT. Steyskal's procedure modifies the mode excitation coefficients digitally and obtains a radiation pattern with angular dependence independent of frequency. Experimental data showed a sequence of three patterns at different frequencies (4, 5, and 6 GHz) with essentially the same patterns.

Methods of Analysis

The analysis of conformal antennas and arrays is undertaken with a variety of methods, depending upon whether the antenna or array dimensions are small with respect to the platform radius of curvature or whether the platform itself is large or small with respect to the operating wavelength. Full numerical solutions (moment method, finite element, or finite difference methods) are still not practically applied for electrically large host bodies, and to date, hybrid methods have proven more useful for these. Array analysis involves an additional complication, in that the interaction between elements, or mutual coupling, must be included in the solution for the fields and currents. This analysis is also very dependent upon the host body dimensions and relative curvature.

Historically, the first methods to find utility were based on integral equation solutions. These pertained to structures like spheres, cones, and infinite cylinders for which full Green's functions exist. They have become very practical to solve using the numerical method of moments (MOM) algorithms.¹³⁻¹⁶ The need to analyze antennas on dielectric substrates has led to the use of spectral methods that have become practical because of the increased computing power now available.¹⁷⁻¹⁹ These conformal structures are analyzed by MOM using some form of a spectral Green's function and matching to boundary conditions either in the spectral domain or after transforming back to the spatial domain.

Descardecì and Giarola²⁰ combined the cavity method with the use of the dyadic Green's function for a perfectly conducting cone, to obtain impedance and radiation patterns for microstrip patch antennas on cones. They assumed that the radius of curvature and cone tip distance was large compared to the wavelength. A related approach, but one not requiring a

geometry with an exact Green's function, allowed Jin et al²¹ to evaluate the radiation from microstrip elements and arrays on cylindrical bodies of arbitrary cross section. In this case the cavity problem is solved with the finite element technique, while the external fields are obtained using a method of moments solution based on reciprocity.

Kildal and Sanford²² and Sipus et al²³ have developed software using the spectral domain method of moments techniques for cylinders of arbitrary cross section, including multiple dielectric layers. They have demonstrated the technique for spherical structures as well. More general shapes have been studied using the free space Green's function and the method of moments using combined field integral equations as well as magnetic and electric field integral equations where appropriate. The Fast Illinois Solver Code (FISC) was developed to treat large problems using the iterative conjugate gradient method and fast multiple techniques. These methods are discussed in several references.^{24,25}

Elements and arrays on generalized surfaces have also been analyzed using the finite difference time domain (FDTD)^{26,27} and finite element (FEM)^{28,29} methods. These methods both offer the flexibility to treat elements on arbitrary three-dimensional surfaces and including dielectric volumes.

Analytical results for antennas on electrically larger bodies have been obtained using a combination of MOM or finite element techniques³⁰ plus quasi-optical techniques. Early work had its origins in the use of the geometrical theory of diffraction (GTD) for simply computing single-term mutual coupling between elements on general convex cylinders and on cones^{31,32} and grew into methods that used GTD to compute the local fields for MOM solution.

More recent work^{33,34} extends the utility of the hybrid methods using new Green's functions developed from the uniform theory of diffraction (UTD). Demirdag and Rojas³⁴ used these Green's functions for evaluation of the mutual coupling between elements on a uniformly coated, perfectly conducting, but otherwise arbitrarily shaped convex surface. The procedure uses generalized high frequency UTD solutions for circular cylinder and sphere to develop solutions for the arbitrarily shaped convex surface via the local EM wave propagation at high frequencies. The demonstrated example evaluated coupling between current elements on a dielectric coated circular cylinder with inner radius 3λ and a coating 0.06λ thick. The coating dielectric constant ϵ_r was 3.25. These results compared well against the exact eigen function expansion for elements greater than 0.5λ apart.

Persson and Josefsson,³⁵ also using UTD-based techniques, investigated the mutual coupling of apertures and arrays of apertures in circular cylinders. The accuracy of this approach was such as to demonstrate agreement with measured data down to the -60- to -80-dB levels. These and other significant results are also recorded in the book by Josefsson and Persson.⁷ Figure 22-7 shows the cylindrical array used to evaluate coupling and array performance. This array has 54 azimuth polarized elements arranged in three rows conformal to a cylinder. The array is 600 mm in diameter. The authors measured mutual coupling and other data.

22.3 ANTENNAS AND ARRAYS ON CYLINDERS

Wide Angle Coverage with Fuselage-Mounted Arrays

One of the major applications for vehicle arrays is for aircraft-to-satellite communications, for which the antenna system is often required to provide coverage throughout the entire hemisphere, usually with circular polarization and including substantial gain at the horizon. Figure 22-8 shows several fully electronically steered arrays, two of which are conformal, while the third is a low-profile, four-faced array.

FIGURE 22-7 Array of 54 azimuthally polarized waveguide apertures (Courtesy of Ericsson Microwave Systems, AB, Goteborg, Sweden)

The use of a single array (see Figure 22-8a) is very appealing provided that gain-contour requirements can be met. Unfortunately, this means that the array must scan from zenith to horizon in all planes. The following illustrates some of the gain limitations for an array scanned from zenith to the horizon.

In an infinite two-dimensional array with no grating lobes, the pattern directivity for a perfectly matched aperture varies like $\cos \theta$. If the array mismatch is not corrected as a function of scan angle, the gain will vary according to the expression

$$(|1 - |\Gamma|^2|) \cos \theta$$

For finite arrays the beamwidth in the plane of scan varies much like $\sec \theta$ except near end fire. The elevation beamwidth δ for an array scanned to 90° (horizon) is given³⁶ approximately by the equation below for column and two-dimensional arrays:

$$\delta = \sqrt{\frac{4\pi}{C} \left(\frac{\lambda}{L_1} \right)}$$

Here L_1 is the length of the array in the end-fire direction, and C is the constant that varies between 3.5 and 7, depending upon phase velocity and the array distribution. If you

FIGURE 22-8 Conformal and low-profile arrays for hemispherical coverage: (a) large array on top of fuselage, (b) array conformal to side of fuselage, and (c) four-faced array

assume an azimuth beamwidth of approximately λ/L_2 is the array dimension perpendicular to the plane of scan, the directive gain at end fire is approximately

$$D = 4\pi \frac{L_2}{\lambda} \frac{1}{\delta} = \sqrt{4\pi C} \left(\frac{L_2}{\lambda} \right) \sqrt{\frac{L_1}{\lambda}}$$

Since the directivity is multiplied by four for an array of slots over a perfect ground plane (and the beamwidth is halved), the ratio of directive gain at end fire to directive gain at broadside (with perfectly conducting ground) is approximately

$$\frac{D}{D_0} = \sqrt{\frac{C}{\pi}} \sqrt{\frac{\lambda}{L_1}}$$

The result for an array of elements other than slots is different by a constant.

This equation shows that for any given broadside directive gain D_0 , it is advantageous to reduce L_1 (the array projection in the end-fire direction) as much as possible,

for that minimizes scan loss. It also indicates that larger arrays undergo increased scan loss. For example, a square array with 20-dB gain at broadside should exhibit a directivity degradation of 1 dB at end fire, but for a 30-dB square array a 4.5-dB falloff is expected.

Unfortunately, this decrease in directivity is only one of the factors tending to make scanning to end fire inefficient. Other major factors are diffraction and scattering due to the vehicle on which the array is mounted (see Section 22.1), element-pattern narrowing, and array mismatch due to mutual coupling.

Other options for hemispherical coverage shown in Figure 22-8 include the use of multiple conformal arrays (see Figure 22-8*b*), one on each side of the vehicle to provide good coverage except in conical regions near the vehicle nose and tail, or a four-faced array (see Figure 22-8*c*), perhaps with adequate coverage throughout the hemisphere with a relatively streamlined geometry. Multiple planar arrays are often used for ground-based-radar coverage, and Corey³⁷ gives a convenient graphical technique for determining the vertical face tilt and element packing geometry for planar antennas with given scan limits.

Figure 22-9 shows contours of constant projected area for any of the configurations of Figure 22-8, using the coordinate relationships that follow, for a planar array tilted at angle δ from the vertical:

$$\Theta = \cos^{-1} [v \cos \delta + c \sin \delta]$$

$$\phi = \tan^{-1} \left[\frac{u}{-v \sin \delta + c \cos \delta} \right]$$

where $u = \sin \theta \cos \phi$, $v = \sin \theta \sin \phi$, and $c = \cos \theta$ is the array projection factor. In general, the array projected area does not equate directly to relative gain because of array mismatch,

FIGURE 22-9 Coverage diagrams for a variety of tilted planar-array faces: (a) arrays tilted to $\delta = 45^\circ$ with array normals at $\phi = 0^\circ$ and 90° and array with normal at zenith ($\delta = 90^\circ$) and (b) arrays with normal at $\phi = 90^\circ$ and at $\delta = 0^\circ$ and 20°

element-pattern variation, and polarization effects, but it does provide a useful upper bound. This optimum-gain contour, normalized to peak, is given by

$$\frac{P}{P_0} = 10 \log c$$

Figure 22-9a shows three contour plots of this ratio: two for arrays mounted at $\delta = 45^\circ$ and one with $\delta = 90^\circ$. The dotted line is the gain contour for an array with its boresight at zenith ($\delta = 90^\circ$) and corresponds approximately to Figure 22-8a. The solid curve corresponds to an array located as in Figure 22-8b or a side face of the four-faced array of Figure 22-8c mounted with $\delta = 45^\circ$, $\Phi = 0^\circ$. The dashed curve is for an array with its boresight in the $\Phi = 90^\circ$ plane and corresponds to the end face of Figure 22-8c. Combining the solid and dashed curves, as is done for the four-faced array, indicates that an array with these four faces would cover the upper hemisphere with only a 3-dB projected area falloff near $(\Theta, \Phi) = (90^\circ, 45^\circ)$, while the array with $\delta = 90^\circ$ would have less gain for all $\Theta > 60^\circ$, and thus has its lowest gain over the large area near the horizon.

A more streamlined four-faced array is obtained by reducing the front and rear faces to about one-half of the size of the side faces. In this case it is convenient to mount these arrays with their boresight direction closer to the horizon because the larger side faces provide sufficient gain at the higher elevation angles in the $\Phi = 90^\circ$ or 180° planes. Figure 22-9 shows two gain contours for full-size arrays with $\delta = 20^\circ$ (solid) and $\delta = 0^\circ$ (dashed) for a front-face $\Phi = 90^\circ$. By evaluating the coverage contours in conjunction with those of the solid curve from Figure 22-9a (side face), you can compare the available coverage for a four-faced array with a variety of array sizes and elevation angles. If the front and rear faces are selected to be smaller than the side faces, the corresponding number of decibels (for example, 3 dB for one-half of the area) must be subtracted from the values on the contour lines.

As an example, you can show that, with half-area front and rear faces and using $\delta = 20^\circ$ for these end faces, the array system can scan throughout the hemisphere with a minimum projected area of approximately -4.5 dB with respect to the maximum.

Figure 22-9 can also be used with $\cos^2 \theta$ element patterns by doubling all the decibel ratios given in the figures or with any other assumed element patterns that are independent of Φ by making the appropriate change of scale.

Arrays mounted above a cylindrical surface are subject to pattern deterioration owing to multipath scattering from the surface. Pattern calculations for a four-faced array (see Figure 22-8c) have been carried out by using geometrical optics³⁸ using expressions from the work of Kouyoumjian and Pathak.³⁹ Figure 22-10 shows the computed gain for both polarizations by using a small array mounted at 45° from the top of a large cylinder. The indicated pattern ripples are the result of a specular multipath from the cylinder surface, and the figure shows that in this particular instance these ripples do not materially alter the elevation-plane coverage of the array.

Satellite communication from airborne terminals at EHF also requires near hemispherical coverage. Again the cost of two-dimensional scanning has stimulated development of alternative electromechanical arrays. Figures 22-11a and b show a sketch of one concept⁴⁰ for providing elevation electronic scan from zenith to 20° from the horizon, and electromechanical scan in the azimuth plane. The antenna array is tilted 35° from the horizontal and mounted below the surface of the cylinder. It is mounted off-center in a circular frame, and the whole system is rotated to provide 360° of azimuth coverage. The array requires an oversize hole in the fuselage in order to provide coverage to the 20° angle. Figure 22-11b shows a brassboard demonstration array by Hazeltine Corporation following this concept. The array receives at 20 GHz and transmits at 40 GHz. The brassboard model shown in the figure obviously has significant intrusion (over two feet), but a later version of this array

FIGURE 22-10 Multipath effects on a tilted four-faced array

was designed to be about 11 inches deep. The 6- by 14-inch aperture is a unique design incorporating both frequencies in an interlaced configuration of slots. Key features of the design include parallel plate feeds, interlaced linearly polarized slot elements, and a dual frequency meander line polarizer with good characteristics throughout the $\pm 35^\circ$ elevation scan, and a dual-frequency radome with $0-70^\circ$ scan requirements. Sidelobes are less than -17 dB relative to the main beam peak.

Figure 22-12 shows an electromechanically scanned array called a VICTS (variable inclination continuous transverse stub) array, an innovative and practical solution for providing scan in two planes from a single horizontal array. The center photo of a Ku-band array shows a number of long slots cut through the surface of a circular plate. These slots are very short parallel plate waveguides that support only the lowest order (TEM)

(a)

(b)

FIGURE 22-12 Mechanically scanned VICTS array (Courtesy of ThinKom Solutions, Inc., Torrance, CA)

waveguide mode. A second plate is indicated in the sketches to the right and left. This plate can rotate with or independently from the slotted plate. The sketch below the photo shows the upper plate as a series of radiating waveguide stubs of height L and width H being fed by a parallel plate waveguide of height B . This is the basic configuration of the continuous transverse stub array that has been the subject of several publications and patents.^{41,42} The dashed and dotted lines indicate different directions (and wavelengths) of the incident waves in the parallel plate region. The wavefronts indicated by dashed lines are parallel to the rows of stub radiators (slots), and so radiate broadside. The wavefronts shown by the dotted lines are at an angle to the stubs and excite radiation from the stubs that have a progressive time dependence to scan the stub radiation from broadside.

In the VICTS array this action is obtained by rotating the bottom plate relative to the top plate and can scan to 80° from the broadside. Rotating both plates together will then scan the radiated beam in the azimuth plane.

Fully electronically scanned arrays have also been developed for airborne satcom at SHF and EHF frequencies. Since in most cases the aircraft radii of curvature are large compared with the array size, the arrays can be planar and flush mounted without having to conform to the cylinder. This technology has been under development since the mid-1980s by the U.S. Air Force and NASA. These developments have led to a full line of arrays, including the three satcom receive arrays shown in Figure 22-13 at 8, 12, and 20 GHz.

FIGURE 22-13 Low-profile arrays for satcom receive applications (Courtesy of Boeing Aircraft Corporation)

The small arrays shown here have only 16 elements and depth of 1.4 inches at 8 GHz, 0.94 at 12 GHz, and 0.75 inch at 20 GHz. The array elements are dielectric loaded circular waveguides excited by switchable left- and right-handed circularly polarized modules that have four phase shifter bits and an extra bit to select the polarization.

Elements and Arrays on Cylinders

When the array size approaches the vehicle radius of curvature, the behavior of the array element pattern becomes very different from either the isolated element pattern or the element pattern in a planar array. This property is well documented in the case of circular and cylindrical arrays, which have been the subject of more detailed studies than other conformal arrays. It has long been known that by using the symmetry properties of the array, you can avoid the solution of N simultaneous integral equations for an N -element circular array. Instead, you can superimpose the solution of N independent integral equations, one for each of the solutions with periodicity $2\pi/N$. This method has been used by Tillman⁴³ and King et al⁴⁴ for dipole and monopole arrays and by Borgiotti and Balzano¹³ for waveguide arrays for active elements covering a sector on an infinite cylinder. The results of these and other theoretical studies have revealed the existence of potentially severe ripples in cylindrical-array element patterns, as shown in Figure 22-14a. Sureau and Hessel¹⁴ have used asymptotic methods to show that the radiated pattern can be considered the superposition of a space-wave contribution and several creeping waves that propagate around the cylinder and radiate away from the cylinder in the forward direction. The space-wave and actual patterns are shown in the figure for radiation at two different angles θ measured from the cylinder axis. The ripple amplitude decreases with cylinder radius and increases with frequency. The work by Herper et al,¹⁶ indicated in Figure 22-14b, has shown that smoother element patterns can be obtained by limiting element spacing to $\lambda/2$. The improvement is attributed to the fact that the interference of the fast creeping-wave grating lobe¹⁶ with the direct ray decreases as the azimuth spacing is reduced and disappears at 0.5λ . This work showed that low-sidelobe circular arrays are feasible with proper concern for element design.

With active control, conformal cylindrical arrays can operate in omnidirectional or directional modes, achieving coverage over most of the sphere. However, to achieve efficient scanning it is necessary to include mutual coupling effects in element and grid design.

FIGURE 22-14 Circumferential element patterns: (a) waveguide array on cylinder (after Sureau and Hessel¹⁴ © Artech House 1972) and (b) dipole array in cylinder (after Herper et al¹⁶ © IEEE 1980)

FIGURE 22-15 Cylindrical array of microstrip patches (after Löffler et al.⁴⁵ © IEEE 1999)

Figure 22-15⁴⁵ shows an example of a small dual function array of microstrip patches mounted on a circular cylinder. The modeling was accomplished using a spectral Green's function and the method of moments.

The array consists of eight vertical subarrays of two elements each and operates at C-band over more than 19 percent bandwidth. Each subarray has 10–11-dB gain over the operating bandwidth with a vertical half power beamwidth of 42°. Figure 22-15b shows a cross section of the cylindrical configuration with one element excited. The array consists of a metal cylinder 35 mm in diameter covered by an inner layer of foam 14 mm thick. This layer abuts the microstrip feedlines mounted on a 0.5-mm Duroid substrate. The outer side of the Duroid is metalized, with an aperture that couples the energy from the microstrip line through to the patch antennas. The patch itself has a 4-mm substrate layer of foam separating it from the aperture. The ability to model and build such a complex structure, designing to avoid resonances caused by modes that can propagate around the cylindrical structure, is testimony to the maturity of the analysis and software.

Feed Systems and Commutators for Cylindrical Arrays

Early experimental and theoretical studies concerned arrays that were built with dipole or waveguide² elements, with the array extending completely around the cylinder. Switching was accomplished by a variety of networks that were contained inside the cylinder, some of which are described in this section. Figure 22-16 shows a circular array of waveguide horns developed by the Naval Electronics Laboratory Center⁴⁶ and used in a study of fundamental radiating properties as well as a comparison of several kinds of switching networks. Other studies dealing with full cylindrical or ring arrays are described in the basic reference by Davies.¹²

When the array extends completely around the cylindrical surface, it is necessary to devise a feed network to rotate the illuminated spot continuously through multiples of 360°. As noted by Provencher,² Hill,⁴⁷ and Holley et al.,⁴⁸ a number of mechanical and electrical networks have been devised to accomplish that task. Mechanical commutators such as the waveguide commutator of Figure 22-17a are appropriate for systems with continuous scanning over multiple 360° increments. Such commutators are often seen as viable low-cost solutions for a number of applications, and they can provide scanned patterns relatively free

FIGURE 22-16 Ring array (after Boyns et al⁴⁶ © IEEE 1970)

of modulation effects if care is taken to assure that the rotating (rotor) feed elements have spacing different from those of the stationary (stator) pickup elements. This design procedure can assure that a minimum of elements is misaligned at any one time and so reduces radiation modulation. Power distribution within the rotor is achieved by using coaxial or waveguide corporate networks or radial power dividers.

Other investigators have considered switching networks for commuting an amplitude and phase distribution around a circular array. Giannini⁴⁹ describes a technique that uses a bank of switches to bring a given illumination taper to one sector of the array (usually a 90° to 120° arc) and a set of switches to provide fine beam steering between those characteristic positions determined by the sector-switching network. The circuit for a 32-element array is shown in Figure 22-17b; it requires eight phase shifters and 12 transfer switches (double-pole, double-throw) and achieves sector selection by using eight single-pole, four-throw switches. This network excites an eight-element quadrant of the array that can be moved in increments of one element to provide coarse beam steering. Fine steering is provided by the phase controls.

Several lens-fed circular arrays have been implemented by using *R*-2*R* Luneburg and geodesic lenses.⁴⁸ The *R*-2*R* lens (see Figure 22-17c) described by Boyns et al⁴⁶ forms as many beams as there are elements in the array. However, like all switched lens systems, it does not admit to fine steering (selecting angles with a separation less than the angular separation between radiating elements on the cylinder) unless additional phase controls are added to each element.

As pointed out by Holley et al,⁴⁸ lens systems can be adapted for fine steering by using an amplitude illumination with a moveable phase center. The net result of a progressive phase tilt at the input of the Butler matrix is to synthesize intermediate beams from a composite of the available lens beams and so to provide high-quality fine steering of the lens-radiated pattern.

There have been a number of developments in the area of multimode electronic commutators for circular arrays. These systems derive from techniques similar to that first used by Honey and Jones⁵⁰ for a direction-finding-antenna application in which several modes of a biconical antenna were combined to produce a directional pattern with full

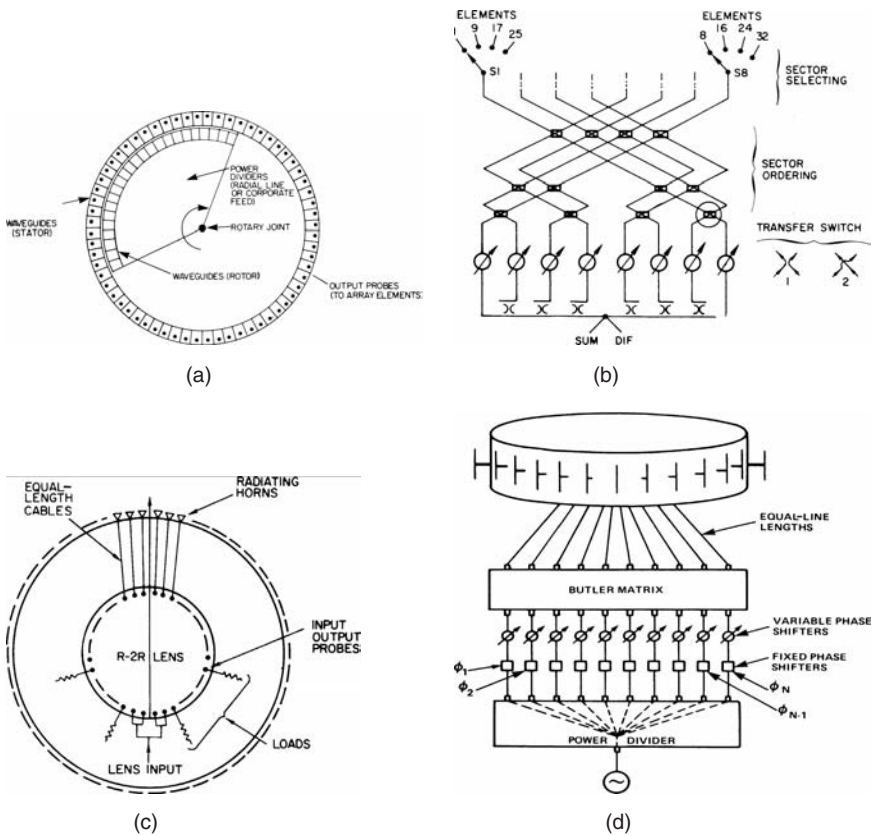

FIGURE 22-17 Circular-array feed systems: (a) commutator (waveguide), (b) switch network (after Giannini⁴⁹ © IEEE 1969), (c) R-2R lens (after Boyns et al.⁴⁶ © IEEE 1970), and (d) matrix scanning system (after Sheleg⁵⁴ © IEEE 1968)

360° azimuthal rotation. Bogner⁵¹ and Irzinski⁵² specifically address the use of such commutators, which must be combined with phase shifters and switches at each element of the array. The phase shifters provide collimating and fine steering, and the switches are used to truncate the illumination so that only a finite sector of the array is used at a time, a procedure that is required for sidelobe control.

Several more sophisticated types of electronic switches for circular arrays are based on a concept, originally proposed by Shelton⁵³ and developed by Sheleg,⁵⁴ that uses a matrix-fed circular array with fixed phase shifters to excite current modes around the array and variable phase shifters to provide continuous scanning of the radiated beam over 360°. The geometry is shown in Figure 22-17d. Skahil and White⁵⁵ later proposed a concept that excites only that part of the circular array that contributes to formation of the desired radiation pattern. The array is divided into a given number of equal sectors, with each sector excited by a Butler matrix and phase shifters. With either of these circuits, sidelobe levels can be lowered by weighting the input excitations to the Butler matrix. The technique of Skahil and White was demonstrated by using an 8 × 8 Butler matrix, eight phase shifters, and eight single-pole, four-throw switches to feed four 8-element sectors of a 32-element array. The design sidelobes were -24 dB, and measured data showed sidelobes below -22 dB.

FIGURE 22-18 Circular array (*Courtesy of Anaren Corporation*)

Rehnmark⁵⁶ showed that you can use the measured phase modes of the received signal to determine its direction of arrival with high accuracy. He observed that since the n th higher order phase mode angular phase progression around the cylindrical or circular array varies n times faster than that of the lowest order ($n = 1$) mode, then the phase progression difference between the $n = +2$ and $n = -2$ modes would be four times as fast as that of the lowest mode, and this rapid phase characteristic should allow four times the angle resolution. He postulated that the resulting ambiguity could then be resolved using the lowest order mode. The circular array of Figure 22-18 is a broadband direction finding antenna based on this concept.

As pointed out by Holley et al.,⁴⁸ lens systems can be adapted for fine steering by using an amplitude illumination with a movable phase center. The net result of a progressive phase tilt at the input of the Butler matrix is to synthesize intermediate beams from a composite of the available lens beams and so to provide high-quality fine steering of the lens-radiated pattern.

22-4 PATTERN SYNTHESIS FOR CYLINDRICAL SECTOR ARRAYS

Among the difficulties with circular sector array synthesis are that the elements of the array have element-pattern maxima at different angles according to their location and that the elements do not lie in a plane. This situation is depicted in Figure 22-19a and precludes use of all the standard synthesis methods. You can, however, control near sidelobes by projecting the array element locations and element patterns onto a plane tangent to the cylinder, as shown

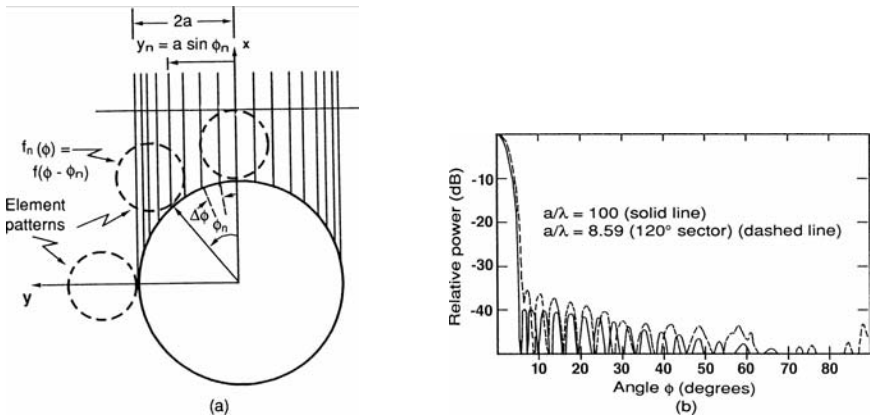

FIGURE 22-19 Synthesis of circular sector array patterns: (a) projection of array-element locations and (b) synthesized patterns with Taylor $n_{\text{bar}} = 8$, -40 -dB sidelobe pattern, $a/\lambda = 100$ (solid), $a/\lambda = 8.59$ (dashed)

in Figure 22-19a. In this process you need to account for the nonuniform spacing that results from the projection, but the element patterns tend to account for this nonuniformity.

Figure 22-19a depicts a circular sector array with elements located equally spaced around the circumferential sector with angular separation $\Delta\phi$. Projected onto the array tangential plane, the element locations of an array are

$$\begin{aligned} y_n &= a \sin \phi_n \\ &= a \sin (n \Delta\phi) \end{aligned}$$

The projection tends to make the points y_n closer together near the ends of the array, but to first-order the element pattern tends to make up for that effect. For relatively large ϕ_n , the projected spacing between elements varies approximately like $\cos \phi_n$, and so the density of elements has a $1/\cos \phi_n$ dependence. If the array element patterns vary like $\cos \phi_n$, then to first-order the projected array weighting will be correct without altering the weights from those of a linear array with omnidirectional element patterns. If the element pattern is very different from a cosine, that fact must be included in the chosen weights.

Figure 22-19 shows several patterns synthesized by projecting a -40 -dB Taylor pattern with $n_{\text{bar}} = 8$ onto cylinders with various radii and 36 elements. Element spacings were restricted to 0.5λ to avoid the grating-lobe sidelobes. The patterns relative to the local cylinder normal at ϕ_n in the ϕ plane have the form

$$f_n(\phi) = \cos(\phi - \phi_n)$$

The two curves show a nearly perfect Taylor pattern at radius $a = 100\lambda$ (solid) and a dashed pattern at $a = 8.59\lambda$ corresponding to an array that occupies a 120° sector of the cylinder. Significant changes in these patterns are beam broadening that results from shortening the array length, and an increased sidelobe level near the main beam, with the first sidelobe starting to merge with the main beam for small cylinders. Even for this small cylinder and the array wrapped over a 120° sector, the pattern is still not severely distorted.

A synthesis method first suggested by Sureau and Keeping⁵⁷ and further developed by Dufort⁵⁸ and Olen and Compton⁵⁹ is readily applicable to conformal arrays on generalized surfaces. The technique uses adaptive optimization algorithms to form the array pattern in the presence of closely spaced sources of interference that are tailored or iterate⁵⁹ to achieve the desired pattern. Figure 22-20 shows results from Sureau and Keeping⁵⁷ for a circular sector array of 32 identical elements disposed over a 120° sector of a cylinder and displaced 0.55λ between elements. The geometry shown in Figure 22-20a shows the 32 excited elements of a 96-element circular array. A total of 372 sources of interference were uniformly distributed outside the main-beam window to control sidelobes. The measured element pattern was used in the calculations. Figure 22-20b shows that increasing the window width produces a set of patterns with progressively lower sidelobes but decreasing aperture efficiency. Sureau and Keeping also investigated varying the interference weights to control sidelobe decay and the use of asymmetric weights for monopulse pattern control.

Other recent developments in synthesis include the use of nonlinear optimization⁶⁰ and least squares iterative procedures for optimizing over pattern parameters and frequency.⁶¹

Figure 22-21 shows results due to Bucci et al.⁶² Illustrating the synthesis of a \csc^2 pattern using an array of 21×15 elementary magnetic dipoles on a cylinder of radius 5λ . The 15 rows of elements are spaced $\lambda/2$ apart in the axial direction, and the 21 columns are spaced 0.7λ apart along the circumference of the cylinder so that an outer semicircle is occupied by the array. The technique employed in this synthesis is an iterative projection method, using a mask function to limit the upper and lower boundaries of the pattern function. In this method, the projection takes place sequentially between two vector spaces, one being the set of the squared amplitudes of all copolar and cross-polar components of all radiated patterns, and the other being the set of all patterns within the mask limits.

FIGURE 22-20 Synthesis of circular sector array patterns using the method of Sureau and Keeping⁵⁷: (a) geometry showing array, jammer locations, and jammer free window and (b) computed patterns and characteristics for various width jammer free windows (a and b after Sureau and Keeping⁵⁷ © IEEE 1982)

FIGURE 22-21 Synthesis of csc^2 patterns via projection (after Bucci et al⁶² © IEEE 1995)

This approach has been used successfully in a number of planar array studies and provides a convenient method with which to synthesize radiation patterns subject to useful constraints like the dynamic range of current amplitudes or reduced number of controls etc.

Figure 22-21a shows the elevation pattern shape and does not demonstrate the conformal synthesis features of the method since this plane is orthogonal to the curvature of the geometry. It does, however, illustrate the use of a mask to bound the synthesis. The procedure synthesized a full triangular shape (see Figure 22-21b) when projected onto direction cosine space. With all its generality, the procedure should find continued application to the synthesis of conformal arrays.

23.1 MILLIMETER-WAVE AND TERAHERTZ APPLICATIONS

There are a number of definitions describing antennas operating in the millimeter-wave (MMW) or terahertz (THz) bands. Most commonly, antennas operating in frequencies whose wavelengths are measured in millimeters (30 GHz–300 GHz) are referred to as *millimeter-wave antennas*. On the other hand, the band between 300 GHz and 3 THz is referred to as the *submillimeter-wave band*, in which the corresponding wavelengths are measured in units less than one millimeter. One can say that a fair amount of freedom has been used in the literature when defining the MMW and THz bands. Some describe a device operating at 24 GHz as a millimeter-wave sensor and those operating around 300 GHz as THz devices. A possible cause for these inconsistencies may be the specialized use of MMW and THz devices. Historically, devices operating in the millimeter-wave, submillimeter-wave, and THz regimes have been limited to specialized applications, likely due to their high cost of realization. Specifically, at these higher frequencies there are a number of challenges, including (1) the availability of sources operating in these bands, (2) fabrication challenges of the small features required for these devices, (3) maintaining tolerance for the small features to achieve repeatable designs, and (4) fabrication costs.

It is certainly well-known that antenna dimensions scale inversely proportional to their frequency. However, at some point, the feature's size becomes a fabrication challenge, and traditional printed circuit-board techniques may no longer be applicable. Nevertheless, recent and ongoing advances in a number of fabrication technologies indicate that low-cost solutions at the MMW and THz frequencies should be possible.¹ Specifically, silicon transceivers can now support frequencies of 60 GHz and higher. That is, with the capability of traditional silicon devices continuing to trend higher,² the challenges of obtaining sources and transceiver ICs is effectively being addressed. To some extent, this moves the challenge in realizing MMW and THz devices to other components, including antennas. This chapter is, of course, specifically focused on the antenna design and fabrication for MMW and THz devices.

Applications for millimeter-wave and THz frequencies include wireless, radar, and imaging (see Figure 23-1). For antennas, it is often found that the design is application-specific where integration, loss, and gain requirements may vary among applications. An issue for the designer is also the allowed frequency band of operation. Specifically, the unlicensed spectrum at 60 GHz overlaps an oxygen absorption band that adds an additional 15 dB/km of attenuation. This is certainly a challenge for long communication ranges,

FIGURE 23-1 Millimeter-wave (MMW) spectrum and applications

but may not be of concern for shorter range applications, as is the case for wireless personal area networks. In fact, this atmospheric attenuation is even desired since it allows for frequency reuse and security of the band by limiting its reach to local areas of operations. From Figure 23-1, imaging applications are typically targeted for bands where there is a local minimum in atmospheric attenuation, as is the case with the 94 GHz and 140 GHz frequency bands. This is important, especially for passive imaging, as the desired signals can be extremely low in power and additional atmospheric attenuation can severely impact their reception. Next we consider the three applications areas separately.

Wireless

As wireless devices become more prevalent and the desire for increased data rates continues, there are challenges in the employed lower frequency spectrum (from 824 MHz for the cellular bands up to 2.4 GHz and 5 GHz for the ISM and 802.11 bands, see Figure 2-4 in Chapter 2). A solution is to use the large amounts of spectrum in the millimeter-wave frequencies. Wireless applications in these bands include wireless personal area networks (WPAN), point to point for backhaul applications, and the extension of fiber and hybrid fiber-coax systems beyond their current reach. The latter presents an advantage over wired networks as it can be cost prohibitive to extend them beyond their current coverage. Specifically, a large portion of unlicensed spectrum is available worldwide around 60 GHz for either WPAN or other applications such as backhaul. In the United States, easily and cheaply licensed spectrum is now available in two 5 GHz blocks near 75 and 85 GHz. It is, however, believed that spectrum targeted for commercial backhaul applications must be licensed so the operator has some recourse in case of interference.

Challenges faced in antenna development for wireless applications may differ significantly. For backhaul applications, the antennas are typically directional and physically large for acceptable performance over 1–2 km in range under typical rain-fade conditions. However, in the case of WPAN, the challenges range from low cost to sufficient gain for acceptable system-level performance allowing for high data-rate connectivity. To achieve multigigabit data rates at reasonable ranges, especially for non-line-of-sight (NLOS) conditions, it has been recently shown³ (using simple channel models) that antenna gains on the order of 20 dBi are likely required. Though these antennas will be smaller, an array may be required to achieve such large gains while accounting for expected chipset efficiencies. Figure 23-2 shows signal-to-noise (S/N) ratio as a function of separation distance under different propagation conditions and transmission systems such as single-input single-output (SISO) and multiple-input multiple-output (MIMO). The propagation channels included in Figure 23-2 include the usual line-of-sight (LOS) with multipaths and the non-line-of-sight (NLOS), referred to as LOS-blocked in the figure. An observation for Figure 23-2 is that MIMO (see Chapter 57) has a clear advantage in achieving higher data rates.

Radars

Millimeter-wave radar sensors are in early deployment for applications such as automotive anticollision systems. Virtually every major automaker now has an optional adaptive cruise control system that may become part of a future automotive safety system for collision warning/avoidance, lane departure warning, blind spot detection, backup, and parking aids. Such systems are already being used for parking assistance. Though there is debate on the future pervasiveness of anticollision systems, it is widely expected that these technologies will make driving safer. For example, without active avoidance, perimeter sensors may detect a situation having a high probability of collision and initiate pre-crash safety steps,

FIGURE 23-2 Signal-to-noise (S/N) ratio at the receiver as a function of separation distance between the transmitter and receiver. An antenna with 20-dBi gain was assumed (the horizontal lines show the required S/N ratios for the indicated data rates and configuration) (after R. M. Emrick and J. L. Volakis³ © IEEE 2006).

including pretensioning of seat belts, adjusting brake line pressure to shorten stopping distance, and so on. As displayed in Figure 23-3, there are a wide range of sensors likely to be used; these include millimeter-wave, optical, and ultrasonic sensors. Sensors operating in the 77-GHz range with a combination of 24-GHz sensors for shorter ranges (see Figure 23-1) are a likely option. Specifically, millimeter-wave frequencies are considered a good choice because they penetrate fog and heavy dust in addition to allowing for high resolution and being small enough so as not to affect vehicle appearance.

FIGURE 23-3 Automotive sensors for advanced safety systems

Imaging

The area of millimeter-wave and THz imaging has seen significant growth in a number of applications. A popular application is security screening for detection of concealed objects such as ceramic knives hidden beneath clothing⁴ (done passively). Another application is the use of passive millimeter-wave imagers for aircraft systems used by pilots to see landing areas under low visibility conditions (fog or sand storms). Such imaging sensors can operate at higher frequencies that extend to THz and may enable a wide range of systems for detection and diagnosis. A great potential for imaging using MMW and THz exists in the medical field. Applications include tumor recognition, disease diagnosis, recognition of protein structural states, detection/imaging of tooth decay, and so on.⁵

23.2 MILLIMETER-WAVE ANTENNAS

As mentioned previously, challenges associated with antennas at high frequencies include fabrication tolerances, efficiency/losses, and cost, though these are all somewhat inter-related. As is often the case, it can be very difficult to optimize each of these parameters simultaneously, and a number of approaches have already been pursued and developed. In this section, we discuss technologies used for the fabrication of different MMW antennas. We discuss these under the categories of (1) waveguide antennas, (2) printed planar antennas, and (3) on-chip antennas, which may be fabricated using micromachining or semiconductor lithography techniques. Here, the first two approaches will be discussed with the category of on-chip antennas being discussed in a later section.

Waveguide Antennas

An approach to minimizing losses in millimeter-wave antennas is to use waveguide antennas. It is well-known that waveguides and waveguide antennas can provide higher performance and lower losses, but they do not typically align well with compact or low-cost solutions. Nevertheless, in this context, one can consider waveguide feeds and horns or other waveguide antennas, but hybrid approaches have also been explored. When fabricating such components for MMW applications, a lower-cost approach is to utilize metalized plastics,⁶ but many question the viability of this approach. Some challenges associated with the metalized plastics include the type of metallization, interfacing with other components, and maintaining electrical continuity. Also, the overall cost of this approach and other measures relating to integration bring additional challenges. For example, the design must insure that under temperature cycling the joining or movement between dissimilar materials does not degrade metallization and metal contacts.

In addition to using metalized plastics to reduce cost, casting, or electroforming, the antenna followed by gold or other plating is a viable alternative. Two millimeter-wave horn antennas are shown in Figure 23-4. The horn on the left is fabricated using precision assembly and brazing/welding techniques, and the horn on the right is fabricated by plating a cast

FIGURE 23-4 Horn antennas, connected to a WR15 waveguide, operating at millimeter-wave frequencies. The horn antenna on the left is precision assembled whereas the horn on the right is cast and plated for lower cost.

FIGURE 23-5 Parallel plate slot array to improve manufacturability. Dielectric constant of the employed material is 2.17 and an efficiency of 29% was achieved (after J. Hirokawa and M. Ando⁷ © IEEE 1998).

base metal. The electrical performance of the two horns shown in Figure 23-4 is very similar (within one to two tenths of a dB). However, casting (with plating) can significantly reduce fabrication cost from one to several orders of magnitude, depending on the fabrication volume.

An example approach to fabricating waveguide antennas for volume manufacturing is to employ parallel plate slot arrays,⁷ as shown in Figure 23-5. In this case, losses may be greater since a dielectric must be used for filling the waveguide. Of course, lower dielectric constants are preferred to avoid further reduction in the metallization dimensions, thus reducing fabrication costs and ohmic losses (issues related to high dielectric constants or thin substrates will be discussed later in more detail).

An additional example of a waveguide feed is shown in Figure 23-6. In this example,⁸ a waveguide is used to feed the microstrip antenna, and this may be a good compromise for certain applications since losses in the MMW feeding networks can be significant. The feed shown in Figure 23-6 is rather standard and employs an aperture in the broadside of the rectangular waveguide positioned under a microstrip antenna. Challenges for an approach like this, as in other cases, are likely to increase as the frequency of operation continues to increase since at higher frequencies, the dimensions of the aperture can become quite small, and placement of the microstrip antenna properly over the aperture can become a dominant challenge.

FIGURE 23-6 Waveguide to microstrip antenna coupling using an aperture at the broadwall to feed the microstrip antenna (after D. Pozar⁸ © IEEE 1996)

Printed Planar Antennas

As may be expected, there is strong interest in printed planar antennas for millimeter-wave applications. At lower frequencies, these are very easy to fabricate and are compatible with other portions of a transceiver that may be implemented on the same substrate allowing for greater integration. There are a range of substrates used for planar antennas, but there are some that appear to have garnered the greatest interest based on the volume of current work and technical publications. The most commonly used substrates are currently low temperature cofired ceramic (LTCC), liquid crystal polymer (LCP), and silicon. Interest in LTCC and LCP is fairly wide because their electrical properties are some of the best at millimeter-wave frequencies and are also well-suited for integration with other portions of a transceiver. Silicon is certainly of high interest for on-chip antenna integration.

FIGURE 23-7 Double slot antenna implemented on an LTCC package (after K. Maruhashi et al⁹ © IEEE 2000)

Packages with integrated antennas using LTCC have already been demonstrated, and there are a number of options available in the type and implementation of printed planar antennas utilizing LTCC. A double slot antenna⁹ on LTCC is shown in Figure 23-7. In this case, the antenna is formed using several layers to produce a multilayer package delivering a gain of 4 dBi for the double slot antenna. This example represents good feasibility for antenna integration with the transceiver package. However, having the antenna and transceiver close to or colocated with the transceiver is not always preferred. Depending on the application and the transceiver, it may be preferable to have the antenna located where it can provide the best performance with the rest of the transceiver, for instance, located near its interfaces with the rest of the system. Having the antennas separated from the transceiver is, of course, common at lower frequencies, but at millimeter-wave frequencies interconnect losses between the transceiver and antenna are of concern. In this case, separations of many wavelengths can be expected for a package of a few millimeters in size. Using more available layers for antenna design with LTCCs is also an option, as demonstrated with the multilayer parasitic microstrip antenna array in Seki et al¹⁰ (see Figure 23-8). This antenna was formed using three LTCC layers and incorporates the feed element and two parasitic element layers. It delivered a measured gain of 7.17 dBi.

In addition to LTCCs, a substrate material that has been gaining interest is the liquid crystal polymer (LCP),¹¹ though LCP has been under consideration for much less time than LTCC. LCP has captured interest due to its good electrical characteristics. They are also considered very stable since LCP does not absorb moisture and is therefore near hermetic.

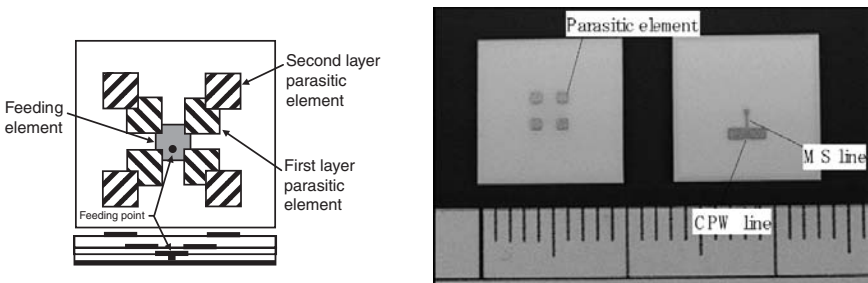

FIGURE 23-8 A multilayer parasitic microstrip antenna array implemented using LTCC (after T. Seki et al¹⁰ © IEEE 2005). Measured absolute gain for this antenna is 7.17 dBi.

TABLE 4-1 Comparison of Substrate Properties for LTCC, FR4, and LCP

	LTCC	FR4	LCP
Relative permittivity	5.6 (20 GHz)	4.5 (1 MHz)	2.9 (20 GHz)
Loss tangent	0.0012	0.02	0.002
Relative cost	Medium	Very low	Low

A comparison of LTCC, LCP, and FR4 is shown in Table 23-1. As shown, LCP has a loss tangent similar to LTCC with a lower dielectric constant. The latter may be an advantage at MMW frequencies, but as compared to LTCCs, it offers fewer dielectric constant choices.

Using LCP substrates with multiple layers, as may be done with LTCCs, a number of antenna possibilities exist. One such possibility is shown in Figure 23-9 where multiple LCP layers have been used to implement a vertical array of spiral antennas to achieve more than 12-dBi gain occupying a top surface area of only 1.2 mm. Additional increases in gain may be achieved by increasing the number of layers and increasing the number of elements. The operation of an array like this is similar to a Yagi-Uda antenna where the ground plane acts as the reflector element and the element above is the driver. Additional spiral elements above the driven element act as director elements. A challenge in this approach is feeding the driver element.

On-Chip Antennas

Since antennas are physically small at high frequencies, overcoming challenges with interconnect losses has forced implementations toward on-chip integration. A number of approaches beyond those that are part of standard packaging techniques (to minimize dielectric and metal losses) have been explored.¹²⁻¹⁵ In order to minimize losses, methods are often used to maximize the portion of the fields that are in air or to maximize the metallization used to print the transmission lines and antennas. However, since the characteristic impedance of transmission line is $Z_0 \approx (L/C)^{0.5}$, and the capacitance increases with the dielectric constant, as the capacitance increases the transmission line impedance is also lowered. To compensate for the increased capacitance, the width of the microstrip line can be decreased. This does raise the line impedance but also

FIGURE 23-9 High-gain antenna utilizing multiple LCP layers to form a vertical array of spirals over a ground plane. The achieved gain is 12.3 dBi with a top surface occupying 1.2 mm, and computations were carried out using the Remcom XFDTD (after R. M. Emrick and J. L. Volakis³ © IEEE 2006).

FIGURE 23-10 Transmission line losses in dB/mm using thin dielectrics. The SiO₂ substrate thickness 0.3 μm is representative when implementing 50 Ω transmission lines in the top layers of silicon wafer processes. Losses for thicker GaAs substrates are also shown for comparison (use of higher dielectric constants produce similar effects).

increases ohmic losses associated with the transmission line. Figure 23-10 shows loss contributions due to thin dielectrics for a microstrip transmission line using simulations. The figure highlights the effects of ohmic losses and how these can become dominant as frequencies are increased (assuming a substrate with reasonable loss characteristics). The assumed relatively thin SiO₂ layer of 0.3 μm is consistent with the upper layers available for the transmission line as part of a silicon process. For reference, losses of ~ 0.2 dB/mm are expected when using gallium arsenide (GaAs) with a commonly used substrate thickness of 100 μm .

An approach for reducing losses in structures and components by reducing the substrate dielectric used¹² is shown in Figure 23-11. By creating an air cavity below the structures, both the dielectric and ohmic losses can be reduced. Air cavities can be created to form such structures either by etching or by micromachining away materials from a thick substrate. Alternatively, the desired devices and components can be placed on a thin membrane either before or after being applied to a supporting structure. It is not clear that approaches like this will lend themselves to low-cost, high-volume manufacturing, though they are clearly of interest for specialized lower-volume applications. For such approaches to be viable for high volume, they should also be compatible with standard semiconductor processing. Additional issues may relate to the device packaging for long-term reliability as moisture or other contaminants that enter the air cavity can significantly affect performance. A larger scale example of this approach is shown in Figure 23-12. Figure 23-12 shows a two-dimensional array fabricated so the antenna element is suspended on a membrane over a cavity shaped as a horn. This approach allows for reduction in both dielectric and ohmic losses.

FIGURE 23-11 Approach for reducing losses by increasing the air volume near the structure or components of interest (after C. Nguyen et al¹² © IEEE 1998). This may have the effect of reducing dielectric losses in addition to possibly reducing ohmic losses due to decreased distributed capacitance.

FIGURE 23-12 Two-dimensional array utilizing membranes and air cavities to reduce losses (after G. Rebeiz et al¹³ © IEEE 1990)

The horns were fabricated by anisotropic etching of the silicon in an ethylenediamine-pyrocatechol solution. The etchant used forms pyramidal holes bounded by $\langle 111 \rangle$ crystal planes in $\langle 100 \rangle$ silicon. The flare angle of the horn was fixed at 70.6 degrees by the orientation of the crystal planes. This angle was larger than desired to accommodate the employed fabrication method. It is possible that the horn angle could be better controlled if reactive ion etching or ion-beam milling were used. In this case, the membrane was produced by depositing a silicon oxynitride layer on the front wafer using chemical vapor deposition. The silicon was then etched away to leave the free-standing membrane. It is noted that for the membrane to be flat and rigid, it must be in tension.

An additional potential challenge associated with on-chip antennas is the limitation in dielectric properties and thickness. Silicon substrates have a relative permittivity of about 11.7 but the resistivity of the substrate can vary. Of course, substrates are limited to those available for already established semiconductor processes, and wafer thicknesses may also be limited to stay with standard processing. Typical high-volume silicon substrates may have resistivity on the order of $10 \Omega\text{-cm}$, though higher resistivities of $1 \text{ k}\Omega\text{-cm}$ or more are available but are more expensive and may not be available in large diameters. Of course, substrate thickness and the dielectric constant can effect antenna performance beyond dielectric and ohmic losses. For example, if the substrate thickness and dielectric constant are not chosen properly, surface waves and other substrate modes can significantly effect efficiency and bandwidth¹⁵ (see Figure 23-13). Conditions that generate surface wave and substrate modes can significantly affect performance so they should be avoided.

Antennas implemented at high frequencies tend to be relatively simple geometries and try to maximize metallization to minimize ohmic losses. Figure 23-14 is an example of an edge-fed microstrip antenna that can be implemented in a very small space by trading bandwidth.

FIGURE 23-13 Formation of surface wave and other substrate modes can effect performance of on-chip antennas (after N. Alexopoulos et al¹⁵ © IEEE 1983)

FIGURE 23-14 Example layout of an edge-fed element on silicon for compact on-chip antennas. When minimized in size, the antenna element measures only $360\ \mu\text{m} \times 135\ \mu\text{m}$ delivering 3.2-dBi gain and a 3-dB bandwidth of 17%.

This microstrip antenna can be optimized to occupy only $360\ \mu\text{m} \times 135\ \mu\text{m}$ and deliver a gain of 3.2 dBi with a corresponding 3-dB bandwidth of 17%. Compact antenna elements such as this can be used to realize higher gain by implementing an array of on-chip elements.

Another antenna element that shows promise is illustrated in Figure 23-15. This element is formed from a half circle and incorporates a tuning slot that allows this element to be tuned so it can be impedance-matched more easily. This is another example of a broadband element that can be implemented in a relatively small space in trade for bandwidth. Though this element is larger than the previous example, it can be designed to achieve a 3-dB 17% bandwidth gain of 3.8 dBi while occupying only $480\ \mu\text{m} \times 240\ \mu\text{m}$. Each of these approaches can be implemented with much greater bandwidth if larger physical sizes are acceptable; each of these example microstrip antenna elements offers a wide range of usefulness and can be tailored for a particular application where size, bandwidth, or gain may be the most important design parameter.

FIGURE 23-15 Example of a millimeter wave antenna comprised of a half-circle element with a tuning slot. When the size is minimized, the element measures $480\ \mu\text{m} \times 240\ \mu\text{m}$ delivering a gain of 3.8 dBi with a 3-dB bandwidth of 17%.

22.3 SUBMILLIMETER-WAVE AND TERAHERTZ ANTENNAS

Approaches used at submillimeter-wave and THz frequencies are very similar to those already discussed. Fundamentally, the fabrication challenges and losses are the same but more of an issue at THz frequencies. At submillimeter wavelengths, fabrication techniques are limited to micromachining and semiconductor lithography or equivalent due to their smaller dimensions. Interconnects between the antenna and other components such as detectors (see Chapter 32) are also more challenging, leading to higher levels of integration to achieve acceptable performance.

An example of a log-periodic antenna fabricated on a thin membrane with an integrated detector operating up to 700 GHz¹⁶ is shown in Figure 23-16. As shown, membranes and air cavities along with an integrated antenna detector were employed to achieve performance. Antennas operating at frequencies greater than 1 THz have also been demonstrated. As an example, a log-periodic antenna element with a lens coupled to a hot-electron bolometer was fabricated and shown to operate from 1–6 THz¹⁷ (see Figure 23-17). Again, lithography requirements are not achievable with standard printed wiring-board techniques, and integration with other components is required to minimize interconnect losses.

FIGURE 23-16 Example antenna on a thin membrane integrated with a detector operating up to 700 GHz (G. Rebeiz et al¹⁶ © IEEE 1987). As the operational frequency increases, higher levels of integration are required to avoid degradation due to interconnects.

FIGURE 23-17 Log-periodic antenna element with a lens coupled to a hot-electron bolometer for operation at 1–6 THz (after A. Semenov et al¹⁷ © IEEE 2007)

FIGURE 23-18 Micromachined waveguide antenna for 1.6-THz operation (after J. Bowen et al^{18,19} © IEEE 2006). A gain of about 13 dBi was achieved.

Micromachining has also been used to successfully fabricate THz antennas. A 1.6-THz waveguide antenna fabricated using micromachining^{18,19} is shown in Figure 23-18. Though there is some room for improving the performance of this antenna, micromachining techniques show promise for THz antennas. A gain of about 13 dBi was achieved in this prototype. As in other cases, volume fabrication has not been demonstrated, but it does show promise for specialized applications within the THz frequency range. An alternative to micromachining is standard semiconductor lithography techniques to create repeatable feature sizes well into the submicron range.

In addition to the above, other fabrication approaches have also been explored for THz antennas. One such approach is the photoconductive antenna,²⁰ also known as a photoconductive switch and shown in Figure 23-19. In this case, electrodes are formed on a semiconducting photoconductive film. The film is (in most cases) a III-V semiconductor such as GaAs. The photoconductive antenna can be considered as a dipole of length L with its resonance shifted due to the refractive index of the semiconductor (GaAs at THz frequencies has a refractive index of $n = 3.4$). For operation, a voltage is established across the electrical contacts and the excited carriers are accelerated by the electric field during the optical excitation pulse. This results in a short broadband electromagnetic pulse in the THz region. When used as a receiver, during the optical pulse the excited carriers are accelerated by the electric field component of the THz pulse, which creates a measurable current. The receiver is, as usual, connected to a current amplifier across the terminal electrical contacts.

FIGURE 23-19 Photoconductive antenna to generate and transmit or receive THz signals (L is antenna length)

24.1 INTRODUCTION

There are many reference books on antenna theory and design,¹⁻¹⁷ but very few are devoted to wideband phased arrays. A complete and comprehensive treatment of all aspects of phased arrays is given by Hansen in *Phased Array Antennas*¹⁷ and in his previous works. The array antenna field is considered to be mature and well established; however, recent years have seen a rapid growth in the development of ultra-wideband arrays, primarily driven by the requirements of modern radar and Electronic Warfare (EW) systems that require very wide bandwidth from UHF to high X-band. Also, there is an increasing need to consolidate and reduce the number of antennas on an airborne and shipboard platform due to limited space in accommodating an ever proliferating number of sensors. Furthermore, with the advent of channelized digital receivers backed by a massive amount of computing power, adaptive digital beamformers with unique processing features have become a reality and hence have received wide attention in the defense industry. To achieve these goals, an ultra-wideband aperture capable of supporting more than 10:1 band is desired. A great deal of progress has been made, so this chapter reviews the design concepts of wideband arrays and updates the progress reported by various groups.

Section 24.2 reviews the definition of bandwidth, principles of wideband arrays based on the continuous current sheet model by Wheeler,¹⁸ and the rigorous formulation recently developed for practical array design. Section 24.3 discusses recent progress of wideband arrays using “connected” elements. Section 24.4 examines the ground plane effects, and Section 24.5 presents some prototype examples of wideband arrays, including single-pol (polarization) and dual-pol apertures such as long slot and low profile egg-crate designs.

24.2 WIDEBAND ARRAY CONCEPTS

Definition of Wideband

To begin, we should define a more useful term than conventional “bandwidth” for wideband applications. For all practical purposes, the bandwidth of an array antenna is defined here by the frequency range over which the input VSWR is less than 2:1. Typical (fractional) bandwidth of many existing radar systems is on the order of 10 to 20 percent, with the bandwidth defined as

$$\text{Bandwidth (\%)} = 200 \frac{f_2 - f_1}{f_2 + f_1} \quad (24-1)$$

where f_1 is the low end and f_2 the high end of the band. For wideband systems, it is common to specify the ratio of the high end and low end frequency with a factor N , where $N = f_2 / f_1$. For instance, a UHF radar antenna designed for foliage penetration (FOPEN) to detect targets concealed under forests may require a bandwidth ranging from 150 to 600 MHz, which is 4:1 band. On the other hand, a typical high-band EW array may require 3:1 band from 6 to 18 GHz. In such cases, it is more convenient to use the N :1 ratio in the discussion of system requirements and performance. The conversion between the fractional bandwidth and the N factor is given by

$$\text{Bandwidth (\%)} = 200 \frac{N - 1}{N + 1} \quad (24-2)$$

FIGURE 24-1 Fractional bandwidth vs. frequency ratio factor N :1

The percent bandwidth for some typical N factor is shown in Figure 24-1. The fractional bandwidth is meaningful for narrowband systems but not so useful for the wideband cases. For instance, a very challenging 10:1 band translates into a bandwidth of 164 percent, while an extremely wideband system (>100 :1) has 200 percent fractional bandwidth as a limit. Hence, the N factor is more suitable for describing a wideband system. A large N :1 ratio usually signifies great difficulty in providing the wide bandwidth for a mission, because the array antenna must be able to support a system where the wavelength varies by a factor of N . It also implies that the array lattice is tight, and the element spacing is limited to about 0.6 wavelength at the high end of the band for grating-lobe-free operation over a wide scan ($\pm 60^\circ$) volume.

We may ask, “how wideband is wideband?” The answer lies in the system requirements and the center frequency of the operation. Depending on applications, 20 percent bandwidth at X-band (10 GHz) is 2 GHz, which may be sufficient to provide adequate range resolution for detection, imagery, and mapping. For more advanced systems, a 2:1 band from 6 to 12 GHz may be more desirable. For direction finding, surveillance, and certain EW applications, a 3:1 band may be required. For low frequency such as UHF, a mere 500-MHz bandwidth centered at 350 MHz implies that the array must operate over a 6:1 band from 100 to 600 MHz. Thus it is harder to get wide instantaneous bandwidth at low frequency. A bowtie element at 400 MHz is on the order of 30 cm, while at 100 MHz it increases to 120 cm. This natural constraint in wavelength is a critical issue to be considered in the design of a wideband array.

While an ultra-wideband aperture offers many desirable features, it is not without penalty and drawbacks. The price to pay is in higher component costs for the RF front-end and in complexity in the dense packaging of the feed networks. The lattice designed for the high end of the band characterized by small element spacing is wasteful for the low end. To support wide band, the feed components including transitions and baluns require extra space and multiple layers of circuit board to support the bandwidth. The extra RF loss associated with these front-end components must be traded off with the benefits gained from the extended bandwidth. Sometimes the bottleneck of a wideband array is not the radiating aperture, but the T/R modules and the associated electronics that must be packed to fit in a tight lattice and to handle the intense heat dissipation in an array environment.

It should be emphasized that a phased array is a periodic structure characterized by certain boundary conditions and eigen (Floquet) modes. A wideband radiating element

does not guarantee that the array will be broadbanded, but a high- Q narrowband (resonant) element will definitely make it difficult for the array to operate over a wide band. Aperture matching is a complicated subject that is configuration and radiator-geometry dependent. For instance, Amitay et al¹⁴ devoted their whole book just to analyzing the waveguide array using eigen mode expansion and matching techniques. However, by and large if the radiating element and the lattice structure do not excite a large number of reactive modes, it is more likely to match the aperture impedance and transmit the power efficiently. In other words, the more an aperture field excited over the array resembles a plane wave, the easier it is to radiate its power into the free space over a wide band.

Current Sheet Model

The basic concept of aperture matching can be dated back to 1948 when Wheeler¹⁸ first discussed the radiation resistance of an infinite array. Later he described the concept of a continuous current sheet model associated with a hypothetical array radiating a TEM wave into the free space.¹⁹ For broadside radiation of any frequency, the radiation resistance of an idealized current sheet backed by a ground plane offset by $\frac{1}{4}\lambda$, is 120π (377) Ω . Conversely, a resistive plane with a surface impedance equal to the characteristic impedance of the plane wave (377 Ω), backed by a ground plane separated by $\frac{1}{4}\lambda$, will absorb an incident plane wave without reflection. The impedance is reduced to 60π (188) Ω if the current sheet is radiating into both directions without the ground plane. For E -plane scan, with an oblique incident angle θ from broadside, the boundary resistance decreases, proportional to $\cos \theta$, due to the cosine projection of the E -field on the aperture (reduction in voltage). For H -plane scan, the boundary resistance increases and varies as $1/\cos \theta$, due to the cosine projection of the H -field on the aperture (reduction in current density). In reality, such an infinite and uniform current sheet does not exist. A more practical case close to the ideal situation is an infinite array of closely spaced conducting strips carrying continuous current over the aperture, as shown in Figure 24-2. An approximate way to produce such a current distribution is to drive each long wire or strip with multiple feed points, effectively exciting an infinite array of connected short dipoles, as depicted in Figure 24-3. The element spacing in both directions must be small, on the order of 0.6λ at the high end of the band, so that it keeps the grating lobes out of the visible space over the desired frequency range and scan volume. The task now is to determine the input impedance of such an array, and to provide a matching network with baluns and transformers to efficiently radiate the power into the free space with minimum reflection over a wide band.

The subject of conducting wires and linear connected arrays has been studied by Hansen,²⁰⁻²⁴ who used the Galerkin moment method to analyze the current distribution over a finite array of such elements. He reported that for arrays of halfwave dipoles the current exhibits strong resonances along the array, with a period of one wavelength. This is apparently due to the edge currents present in finite dipole arrays not being attenuated in connected arrays. For dipole lengths much shorter than halfwave, the current is roughly constant over the entire array. This results in an approximation to the Wheeler's current sheet model, and input impedance ranges from 200 to 400 Ω . Overall, a connected dipole array provides better wideband gain than a corresponding unconnected dipole array.

Characteristics of Wideband Array

Significant insights into the linear connected dipole array can be found in the works by Neto and Lee,²⁵⁻²⁷ who studied the characteristics of an infinite 2D long slot array shown

FIGURE 24-2 An array of conducting strips carrying constant current resembles Wheeler's current sheet model of a wideband array.

FIGURE 24-3 An array of long conducting strips with multiple feed points can produce a quasi-uniform current sheet. Effectively, it is an array of connected short dipoles excited by multiple electric delta current sources.

FIGURE 24-4 An array of long slots with multiple feed points is a conjugate configuration of the connected dipole array.

in Figure 24-4. Each long slot is excited by multiple delta current sources, equally spaced at about 0.6λ with respect to the high end of the band to avoid grating lobes. Since the long slot array is a conjugate (complementary) version of the connected dipole array, it is an array of connected magnetic dipoles, as shown in Figure 24-5. The duality of these two arrays becomes evident when Figure 24-3 is compared with Figure 24-5. Babinet's principle^{28,29} states that the characteristics of these two arrays are identical except that the E - and H -field are interchanged in the radiation. Neto's rigorous analysis of the long slot array provides a solid background to understanding why a phased array with features resembling Wheeler's current sheet model is intrinsically wideband. The treatment is general and applicable to a broad range of related designs including connected dipole arrays. The theory provides physical insights into the characteristics of a wideband array with connected elements. Thus it is beneficial to review the analytic formulation and to identify the key steps in the derivation for better understanding of the subject. This summary is provided for handy reference.

Figure 24-6 shows the geometry of an infinite long slot array in free space without any back (ground) plane. The x -oriented slots are etched out in a conducting plane between two homogeneous dielectric half-spaces of the same permittivity ϵ . The slots are centered at $y_n = n_y d_y$, and the cross section (gap) width of each slot, w_s , is uniform in x and is small in terms of a wavelength at the maximum frequency of interest. Each long slot is excited by an array of y -oriented electric delta current sources (generators) of the same length w_s placed at periodic locations. Each delta source is assumed to be thin, but its actual width, t , in x -direction will be considered later. By invoking the equivalence principle, the slot region can be covered by a metallic surface infinitely thin and perfectly conducting, with an unknown magnetic current distribution $\mathbf{m}_{n_y}(x', y') (= -n \times E / \mu_o)$ including the delta sources just above and below the slot region. These magnetic currents have equal

FIGURE 24-5 A long slot array is effectively an array of connected magnetic dipoles excited by multiple magnetic delta current sources.

amplitudes but opposite signs to ensure continuity of the tangential magnetic field through the screen occupied by the slots. Due to the small gap (w_s) of the slots, the magnetic currents over the slots can be assumed to flow in x direction only (first order of approximation). To derive the unknown magnetic current distribution, an integral equation is introduced to enforce the continuity of the total tangential magnetic field above and below the long slot. The total tangential magnetic field H_t on each side of the slot is the sum of the impressed

FIGURE 24-6 Geometry of an infinite 2D array of long slots excited by multiple feeds spaced at a Nyquist interval, half wavelength at high end of the frequency band of interest

(forced) field H_f and the scattered field H_s radiated by the magnetic current induced on the slots. This leads to

$$H_s^1 - H_s^2 = H_f^2 - H_f^1 \quad (24-3)$$

where 1 denotes region 1 below the conducting screen (slots) and 2 denotes region 2 above the screen. The right-hand side of Eq. 24-3 represents the discontinuity in the tangential magnetic field produced by the impressed current sources, and it is equal to an infinite series of the delta function by Ampere's law. On the left-hand side H_s^1 and H_s^2 are equal but have opposite signs.

The boundary condition yields an integral equation given by

$$\iint_S g(x - x', n_{y_0} d_y - y') m(x', y') dx' dy' = \sum_{n_x=-\infty}^{\infty} f_{n_x}(x) \quad (24-4)$$

with

$$f_{n_x}(x) = I_e \delta(x - n_x d_x) \cdot e^{-jk_{x0} n_x d_x} e^{-jk_{y0} n_{y0} d_y} \quad (24-5)$$

$$m(x', y') = \sum_{n_y=-\infty}^{\infty} m_{n_y}(x', y')$$

where S represents the ensemble of the slots, k_{x0} , k_{y0} are the phase shifts of the impressed excitation, I_e , along x and y , respectively,

$$k_{x0} = k_0 \sin \theta \cos \phi$$

$$k_{y0} = k_0 \sin \theta \sin \phi$$

and $g(x, y)$ is the Green's function of the magnetic field due to a delta magnetic current element. In Eq. 24-5 $m_{n_y}(x', y')$ represents the unknown magnetic current distribution along the n_y -th long slot located at $x_n = n_y d_y$. The left-hand side of Eq. 24-4 represents the difference between the magnetic fields at $x(y = 0, z = 0)$ along the zero-th (central) long slot, radiated by the magnetic currents above and below the slots. The procedure to solve the unknown $m_{n_y}(x', y')$ in Eq. 24-4 is similar to the treatment given by Elliott³⁰ where a moment method is applied to find the current distribution on an electric dipole. The long slot problem can be solved by treating the slot element as a magnetic dipole. In the formulation the total magnetic field radiated by all the slots including the delta sources (generators) at a point in space (x, y, z) is expressed as an integral of the Green's function weighted by the unknown magnetic current distribution $m_{n_y}(x', y')$ from all the slots. The boundary condition is then imposed along the zero-th (central) long slot, requiring that the total tangential magnetic field H_x vanish on the perfect magnetic conductor²⁸ occupied by the slot region except at the gap of each delta source in Figure 24-5. This condition leads to Eq. 24-4. Next, the magnetic current distribution $m_{n_y}(x', y')$ is assumed to consist of two separable parts: a longitudinal x -dependence $v(x')$ and (transverse) y -dependence $m_t(x', y')$. It is the longitudinal part of the magnetic current distribution $v(x')$ that we want to determine, so that the voltage across the slot at x can be computed from the E -field by the relation of

$$m_{n_y}(x', y') = v(x') m_t = -n \times E$$

Then the integral equation is transformed into the spectral domain k_x, k_y on both sides to isolate and find the Fourier components of the magnetic current distribution. The spectral component of the free space Green's function for the magnetic field radiated by a delta magnetic current element (in the x direction) is derived separately, given by

$$G_{xx}^{fs} = -\frac{1}{k_0 \zeta_0} \frac{1}{2} \frac{k_0^2 - k_x^2}{\sqrt{k_0^2 - k_x^2 - k_y^2}} \quad (24-6)$$

This expression is identical to the Green's function for the electric field radiated by a delta electric current element (in the x direction) derived by Lee,³¹ except the ground plane is removed, and $\sin(k_z z')$ is replaced by the decaying exponential term with z' set to zero. In the inverse transform to find $v(x')$, the Poisson sum formula is used in the integration of k_x, k_y to obtain a double series contributed by the discrete Floquet modes in both x and y directions. This is the nature of the periodic structure. These modes represent the spectral lines extracted from the continuum (k_x, k_y) spectrum associated with an isolated single slot element (magnetic dipole). The result for the voltage along the central long slot at $y = 0$ is given by

$$v_0(x) = \frac{d_y}{d_x} \frac{k_0 \zeta_0}{2} \sum_{m_x=-\infty}^{\infty} \frac{I_e e^{-jk_{xm}x}}{(k_0^2 - k_{xm}^2) \sum_{m_y=-\infty}^{\infty} \frac{J_0\left(k_{ym} \frac{w_s}{2}\right)}{\sqrt{k_0^2 - k_{xm}^2 - k_{ym}^2}}} \quad (24-7)$$

where k_0 and ζ_0 are the free-space wave number and characteristic impedance, (120π) 377 Ω , and

$$k_{xm} = k_{x0} - 2\pi m_x / d_x$$

$$k_{ym} = k_{y0} - 2\pi m_y / d_y$$

are the wave numbers of the Floquet modes in the x and y direction. The Bessel function $J_0(k_{ym} w_s / 2)$ results from the integration of the magnetic current across the slot in the y direction, a factor associated with the effects of the slot width. From the voltage expression (see Eq. 24-7), the active impedance of the central slot element at $x = 0$ with normalized input current $I_e = 1$ is

$$z_{in} = \frac{d_y}{d_x} \frac{k_0 \zeta_0}{2} \sum_{m_x=-\infty}^{\infty} \frac{\text{sinc}^2\left(\frac{k_{xm} t}{2}\right)}{(k_0^2 - k_{xm}^2) \sum_{m_y=-\infty}^{\infty} \frac{J_0\left(k_{ym} \frac{w_s}{2}\right)}{\sqrt{k_0^2 - k_{xm}^2 - k_{ym}^2}}} \quad (24-8)$$

where the sinc function results from the integration of the constant magnetic field across a finite gap (t) at the source (see Figure 24-5), accounting for the effects of the feed probe's finite width (see Figure 24-6). The factor $J_0(k_{ym} \frac{w_s}{2})$ stems from the edge condition of the current source across the slot.

FIGURE 24-7 Input impedance of an infinite long slot array as a function of frequency and scan angle in (a) E -plane and (b) H -plane for $d_x = d_y = 0.5\lambda_{\min}$, $\lambda_{\min} = c/f_{\max}$, $w_s = 0.1\lambda_{\min}$, $t = 0.1\lambda_{\min}$

Now the characteristics of a wideband array with connected elements, be they electric or magnetic dipoles, can be discussed in detail. Figure 24-7 displays the input impedance of the array with all the mutual coupling effects taken into account when scanned in the E - and H -planes. One striking feature of such an array is that for frequencies far below the Nyquist limit (when the element spacing dx approaches half wavelength at the high end of the band), the impedance is almost constant, mostly resistive with very little reactance. There is practically no cutoff at the low end of the band for an infinite array without a back plane. The impedance is $(60\pi) 188 \Omega$ at broadside, equal to half the characteristic impedance of the free space, because the array is radiating bi-directionally into two half spaces. The low-frequency characteristics of the array can be obtained by retaining only the lowest-order terms ($m_x = 0$, $m_y = 0$) in Eq. 24-8, leading to a frequency-independent impedance

$$z_{\text{in}} \approx \frac{d_y}{d_x} \frac{\zeta_0}{2} \frac{\cos \theta}{1 - \sin^2 \theta \cos^2 \phi} \quad (24-9)$$

where the Bessel function and the sinc function have been set to unity for small arguments. This first order approximation validates Wheeler's current sheet model, i.e., the scan impedance decreases from 188 to 94 Ω , proportional to $\cos \theta$, in the E -plane scan ($\phi = 90^\circ$), but increases from 188 to 377 Ω proportional to $1/\cos \theta$ in the H -plane scan ($\phi = 0^\circ$). This confirms that an array designed to carry quasi-uniform current distribution over the aperture can operate over an ultra wideband in the sense that the fractional bandwidth $N = f_{\text{high}}/f_{\text{low}}$ approaches infinity for a large array. The scan performance of the long slot array is summarized in Figure 24-8, showing the reflection coefficient of the radiating element as a function of the scan angle θ in E - and H -planes. These curves indicate that the long slot array is well behaved for 2D scan over a wide band and scan volume, as long as the frequency is not too close to the upper limit defined by the Nyquist interval when the element spacing in x and y approaches one half wavelength. Note that Z_{in} is not sensitive to the width of the slot (w_s) or the source probe (t). They do not play a significant role until the frequency approaches the high end of the band. Referring to Figure 24-5 of the equivalent magnetic dipole array, a wider slot width means fatter dipoles with wider bandwidth. Similarly, a wider strip of t (thicker probe at the excitation point) tends to decrease the inductance of the source element. It is the ratio of w_s and t that we need to adjust to cancel the reactance at the feed port.

The imaginary part of the input impedance comes from the square root of Eq. 24-8 associated with the modes of $|m_x|$ and $|m_y| > 0$. These higher order modes are

FIGURE 24-8 Reflection coefficient of the slot element normalized to an input feed impedance of 188 Ω for scan in (a) *E*-plane and (b) *H*-plane

associated with the reactive power stored in the local source region. When the slot is widened to increase the bandwidth, the gap source (excitation probe) also needs to be widened to minimize excessive inductance at the input for high frequency end. An example of achieving this is presented in Lee et al.,³² where the probe is split into two branches to feed the slot.

Ground Plane Effects

The infinite array discussed so far has no back plane, and it radiates bi-directionally. For all practical purposes, however, there is always a metallic back (ground) plane (see Figure 24-9) to reflect the power for maximum forward gain and to shield the aperture from the electronics mounted on the back plate. This back plane significantly limits the bandwidth of the array. The effects can be analyzed by modifying the Green's function in region 1 between the slot aperture and the back plane. In this case, the Green's function in region 1 is given by

$$G_{xx}^1 = -2j \cot(k_z h) G_{xx}^{fs} \quad (24-10)$$

FIGURE 24-9 Unit cell geometry of an infinite 2D slot array backed by a reflecting ground plane

Imposing the boundary condition again, i.e., the total tangential magnetic field contributed from side 1 and side 2 to vanish on the perfect magnetic conductor, we can derive a new formula for the input impedance of the array backed by a ground plane²⁷

$$z_{\text{in}\infty}^{\text{br}} = \frac{k_0 \zeta_0 d_y}{d_x} \sum_{m_x=-\infty}^{\infty} \frac{\text{sinc}^2(k_{xm})}{(k_0^2 - k_{xm}^2)} \times \frac{1}{\sum_{m_y=-\infty}^{\infty} \frac{J_0\left(k_{ym} \frac{w_s}{2}\right)}{k_{zm}} (1 - j \cot(k_{zm} h))} \quad (24-11)$$

As expected, the response is now frequency dependent. When the back plane is about 1/4 wavelength (midband) from the aperture, the back plane presents high impedance to the slots, causing total reflection and maximizing the forward gain. Figure 24-10 shows the complex input impedance of the array, peaking at (120π) 377 Ω around midband with stated array parameters. The analytic results (solid lines) agree well with those obtained by commercial HFSS code (dashed lines). The reflection coefficient plotted in Figure 24-11 shows the bandwidth of the long slot array element connected to a transmission line of 377 Ω characteristic impedance (solid curve). A bandwidth of 47 percent is achieved with 10 dB input match. However, the bandwidth can be improved to 95 percent (3:1 band) by widening the slot width to $0.2 \lambda_{\text{min}}$, changing the back plane distance to $0.4 \lambda_{\text{min}}$, and matching to a 250 Ω input impedance. Arrays with 4:1 bandwidth have been built and tested.^{33,34} The effects of the back plane can be minimized by loading the region in between with resistive or lossy ferrite materials at the expense of efficiency. In fact, an ultrawide bandwidth can be achieved if up to 3 dB loss can be tolerated for some EW applications. In theory, a very compact ultrathin array may be designed to provide greater than 20:1 bandwidth by using next generation meta-ferrite composite materials.³⁵

FIGURE 24-10 Input impedance of an infinite long slot array with a back plane. Solid curves are based on Green's function formulation, dotter curves—computed by HFSS unit cell model. ($d_x = d_y = 0.5 \lambda_{\text{min}}$, $\lambda_{\text{min}} = c / f_{\text{max}}$, $w_s = 0.1 \lambda_{\text{min}}$, $t = 0.1 \lambda_{\text{min}}$, $h = 0.25 \lambda_{\text{min}}$.)

FIGURE 24-11 Reflection coefficient of an infinite long slot array with a back plane (same configuration as Figure 24-9). Bandwidth can be improved to 95 percent (dotted curve) with slightly different array parameters.

Effects of Dielectric Loading

Instead of using a metallic back plane to reflect the power, the array's forward gain can be improved by covering the long slot aperture with a high- κ dielectric radome. Since the dielectric slab is necessarily of finite thickness, reflection will occur at the dielectric-air interface. However, it is well known that a very large bandwidth with negligible reflection can be achieved by using a number of matching layers. For simplicity, we assume that the first dielectric is thick enough to allow the dominant propagating mode to reach the first dielectric interface, and the rest of the matching layers can render the reflection diminishingly small. In this case, as shown in Figure 24-12, the long slot aperture is sandwiched between two half spaces with permittivity of ϵ_{r1} , ϵ_{r2} , respectively. The boundary condition requires that the total tangential magnetic field in the slot, contributed by the magnetic current below and above the slot, vanish. Mathematically, this entails combining the Green's function for region 1 and 2,

$$G(k_x, k_y) = -\frac{1}{k_0 \zeta_0} \left(\frac{k_1^2 - k_x^2}{\sqrt{k_1^2 - k_x^2 - k_y^2}} + \frac{k_2^2 - k_x^2}{\sqrt{k_2^2 - k_x^2 - k_y^2}} \right) \quad (24-12)$$

where $k_1 = k_0 \sqrt{\epsilon_{r1}}$, $k_2 = k_0 \sqrt{\epsilon_{r2}}$. Using this relation, we obtain the input impedance of the array element with dielectric loading given by

$$z_{in}^{2, \text{diel}} = \sum_{m_x=-\infty}^{\infty} \frac{k_0 \zeta_0 d_y \text{sinc}^2(k_{xm} t/2)}{d_x \sum_{m_y=-\infty}^{\infty} \sum_{i=1}^2 \frac{k_i^2 - k_{xm}^2}{\sqrt{k_i^2 - k_{xm}^2 - k_{ym}^2}} J_0 \left(k_{ym} \frac{w_x}{2} \right)} \quad (24-13)$$

FIGURE 24-12 Active impedance as a function of the frequency for an array of long slots between two dielectrics with $\epsilon_{r1}=1$, $\epsilon_{r2}=9$ for broadside radiation, E -plane scan (dashed lines), and H -plane (dotted lines)

As a special case, let region 1 be air and region 2 be loaded with a high- κ material of $\epsilon_r=9$. Now the impedance of region 2 is reduced by a factor of 3, and hence the front-to-back ratio of the power radiated above and below the aperture is equal to 3:1. Also, the input impedance of the array for broadside radiation is lower, equal to $z_0 = 120\pi / (1 + \sqrt{\epsilon_{r2}})$, about 94 Ω for this example, due to the fact that the two regions (like transmission lines) are connected in parallel to the input source. The impedance versus frequency as a function of the scan angle in E - and H -plane is shown in Figure 24-12.

The bandwidth of this radome loaded array will eventually be determined by the number of matching layers employed for a desired front-to-back ratio.

FIGURE 24-13 Reflection coefficients of the array referred to a characteristic input impedance of 94 Ω with $\epsilon_{r1}=1$, $\epsilon_{r2}=9$, $z_0 = 120\pi / (1 + \sqrt{\epsilon_{r2}})$

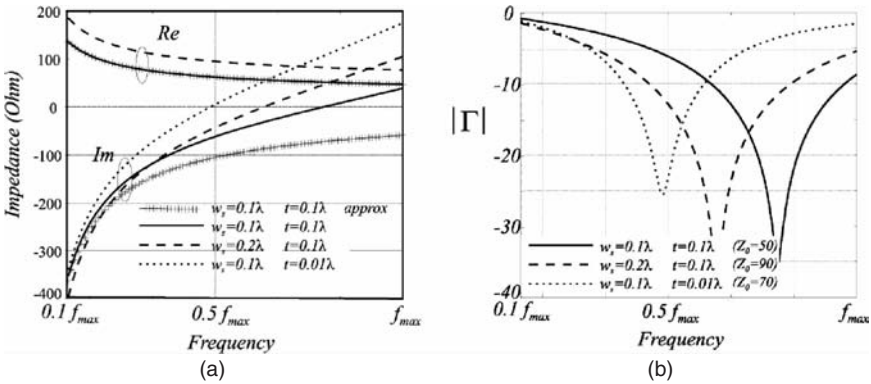

FIGURE 24-14 (a) Input impedance vs. frequency of a single long slot array as a function of slot parameters. Curve with crosses refers to the low-frequency approximation. (b) Reflection coefficient of the array when connected to 50-, 70-, and 90- Ω input line impedance. λ in the figures refers to λ_{min} at maximum frequency.

Finite Array Edge Effects

The wideband array concepts presented so far are based on the theory of an infinite 2D slot array, but all practical designs are finite in dimensions. The truncation effects associated with a finite number of long slots are very similar to those found in standard array antennas.²⁷ The edge effects can be seen by examining a special case where there is only one single long slot in the ground plane. In this case, the edge effects are manifested by a significant amount of reactance in the element's input impedance. The real and imaginary parts of Z_{in} versus frequency are illustrated in Figure 24-14a for various combinations of slot parameters, and the reflection coefficient of the array normalized to various transmission line impedances is shown in Figure 24-14b. Note that the single line source radiates a field that undergoes cylindrical spreading, i.e., the field decays in proportion to $1/\sqrt{\rho}$, with

FIGURE 24-15 Voltage distribution on a single infinitely long slot with 20 feed points. The continuous, dashed, and dotted lines represent the real part, the imaginary part, and the amplitude, respectively. $w_s = 0.1$, $t = 0.1\lambda$.

ρ being the distance from the line source. Although it has reasonable bandwidth, its impedance varies significantly at low frequencies. In this limit, with the linear array scanned in the H -plane (along the slot axis), note several features: (a) both real and imaginary parts of the impedance grow as $1/f$, (b) the real part of the impedance is dominated by the slot's width (dipole width), and (c) the impedance is inversely proportional to the cosine of the scan angle. These drawbacks diminish when additional long slots are added in the other direction to form a 2D large array.

On the other hand, the edge effects will show up in the other direction when only a finite number of feed points are in a long slot. As an example, Figure 24-15 shows a case of 20 feed elements in a single slot, where the truncation causes voltage to oscillate around the solution of the infinite array case. This finding is similar to that reported by Hansen²⁴ for a similar finite array configuration.

24.3 OTHER CONNECTED-ARRAY DESIGNS

The idea of connecting the radiating elements in a planar array was apparently first discussed by Baum et al³⁶⁻³⁸ and Inagaki.³⁹ Baum et al studied arrays of square bowtie elements in a complementary configuration. More recently Kesler et al⁴⁰ and Friederich et al⁴¹ developed the “fragmented” element, which comprises a matrix of conducting and dielectric pixels in the unit cell. The fragmented element aperture is a computer-optimized planar system based on the genetic algorithm. Key to the new design was taking advantage of the mutual coupling of the elements. A prototype 33:1 band array (36 cm \times 36 cm) was demonstrated for 0.3–10 GHz where the aperture includes three layers of metal foil fabricated in computer-designed patterns using printed circuit board technology. Layer 1 is the driven layer of radiating elements connected to the input feed ports, while layers 2 and 3 are parasitic layers with dielectric substrates in between for matching to the free space. In addition to the patterned radiating layers, the antenna is backed by six layers of resistive loading material to eliminate reflections from the back plane. The penalty of the lossy backside is 2–3-dB gain drop over the band.

Another connected-element design was presented by Munk.⁴² As shown in Figure 24-16, it is basically an array of short dipoles connected by capacitors. Since the short dipole has very low inductance, the idea is to load down each short dipole with sufficient capacitance to make it resonate and to use the capacitance to tune out the reactance of the ground plane. The resonance and impedance matching concept is a departure from the wideband continuous current sheet model described by Wheeler,¹⁹ and hence cannot be analyzed by the formulation covered earlier in the “Current Sheet Model” subsection. At very low frequency the capacitor-coupled array may not perform satisfactorily, because the reactance of the capacitor becomes large, thus isolating the dipoles from behaving as connected elements to support continuous currents.

Lastly, another kind of array can be considered as one form of the connected element design. It makes use of the well-known Vivaldi element, which has been extensively studied.⁴³⁻⁴⁸ Figure 24-17 shows a generic Vivaldi design. The quasi-end-fire nonresonant radiator is also referred to as a flared notch or tapered slot element. It is typically fed by a “hockey-stick” balun. The feed point flares from a 50- Ω gap to a large opening, matching to free space's wave impedance of 377 Ω in a square lattice. The tapered slot is essentially a transformer that transfers the power to the tip of the elements where the E -field merges into a plane wave. The element is normally fabricated by cutting a notch in a metal plate and backed by a quarter-wave cavity behind the feed point to improve its forward gain. In most cases, the tapered slot element operates in a region where the element is greater than a halfwave long at the low end of the band, and more than two

FIGURE 24-16 A linear array of short dipoles connected by capacitors, which are inserted to resonate the inductive dipole elements and tune out the ground plane effects

wavelengths at the high end. These elements may or may not touch each other, depending on the element's length, thickness, and local feed geometry of a specific design. Each design must be modeled by custom software such as HFSS, FEKO, or CST to optimize its overall performance. A long tapered slot radiator is not sensitive to the ground plane effect, and it normally supports 4:1 band but can be designed to cover up to 10:1 bandwidth with some gain ripples.

FIGURE 24-17 Tapered slot Vivaldi element typically is $2\text{--}3\lambda$ long at the high end of the band. It supports more than 3:1 band when properly designed.

FIGURE 24-18 Low profile flared dipole (bunny-ear) element is typically is $1/2\lambda$ long at the high end of the band. It produces lower cross-pol in the diagonal plane.

Although the tapered slot has been widely used for various applications, it has some drawbacks. First, the longitudinal currents flowing on the surface of the element are known to produce high cross-polarized components off axis, especially in the 45° diagonal plane. Second, the contiguous metallic structure tends to induce parallel plate modes that propagate along the troughs. One way to suppress these modes is to make the elements thicker and to raise the cutoff frequency of the trough region. However, this makes it difficult to interleave to form a dual-pol aperture in the 3D configuration. Third, the tapered slot is not suitable for low profile systems, such as airborne UHF arrays for foliage penetration synthetic aperture radar (FOPEN SAR) and long-range surveillance radars.

For these reasons, a low profile design has been developed. Figure 24-18 shows a flared dipole, also known as a "bunny-ear" element.⁴⁹ This flared dipole is about $1/2\lambda$ long at the high end of the band and $1/8\lambda$ at the low end, supporting a 4:1 band in a large array environment. The low cutoff is made possible by etching out the conducting area near the feed points. This prevents the low-frequency components from being "short-circuited" by the shunt paths between the adjacent elements. Also, the mutual coupling from the adjacent element on each side is about 180° out of phase at midband, and the magnitude is about half of the passive self-reflection term of the S -parameters (S_{11}). The element can be stamped out in a solid plate, or symmetrically printed on both sides of a low- k substrate such as FR4 fiberglass material. It consists of an impedance transformation feed section⁵⁰ and a pair of flared dipole wings. The radiation efficiency of the element is poor when it is electrically small and isolated in free space. However, the efficiency improves significantly in an array environment with the elements lined up in the E -plane.

24.4 WIDEBAND GROUND PLANE

A wideband array becomes band limited once a ground plane is placed behind the radiating aperture. The degradation is caused by the reflection of the back plane, as discussed earlier in the "Characteristics of Wideband Array" subsection. Ideally, the solution is to

FIGURE 24-19 Ferrite tiles are used in anechoic chamber to absorb power over a wide range of frequency (Courtesy of Fair-Rite Co.).

place a high- Z ground plane⁵¹ behind the aperture to cause total reflection without phase reversal. However, the periodic surface is band-limited due to its resonant nature, so the high- Z ground plane is only useful for narrowband applications so far. A compromise is to use an absorbing material to minimize the reflections from the ground plane, as mentioned in Section 24.3. For certain missions where the bandwidth is more critical than the gain, it may be acceptable to trade off gain, as much as 3 dB, for a wider bandwidth. In this case, the classic Salisbury screen and Jaumann absorber can be used. A comprehensive study of the Salisbury screen can be found in Tuley's chapter of Knott et al's *Radar Cross Section* book,⁵² where extensive discussions on radar absorbing materials (RAM) are given. A general treatment of circuit analog absorbers in the form of multilayer lossy frequency selective surfaces (FSS) is covered in Munk's book.⁵³ Additional references on absorbers are available in the literature.^{54,55} Commercial vendors, such as Emerson and Cuming, also offer multilayer graded absorbers to meet this need. Absorption better than 20 dB over octave band is achievable.

A multilayer resistive absorber normally requires a total thickness of more than $1/4$ wavelength to be effective. For low frequency down to 100-MHz range, this thickness is on the order of 40–80 cm, depending on the dielectric constant of the loading material. Thus alternatives with a lower profile are desirable. One solution is to use ferrite materials. In the construction of a quiet room, a standard approach is to shield the conducting side walls with thin ferrite tiles, as shown in Figure 24-19. The incident impedance of the structure is given by $Z_{in} = j 377 (\mu/\epsilon)^{1/2} \tan(\beta L)$, where β is the wave number in the ferrite material. For a thin slab and low frequency limit, assuming that we are operating in a region where μ is dominated by the imaginary part of the permeability and it has a $1/f$ frequency dependence, the impedance becomes

$$Z_{in} \sim j 377 (\mu/\epsilon)^{1/2} (\beta L) \sim j 377 (2\pi/c) fL (-j\mu''/f) = 377 (2\pi\mu'' L/c) \quad (24-14)$$

By choosing the proper thickness L for a given ferrite material, we can make the factor in the parenthesis equal to unity and the incident impedance equal to 377Ω for low frequency limit. For wide band, a multilayer structure is needed, and it may be feasible to construct a very thin composite absorber using high-index meta-ferrite film material.³⁵ On the other hand, if we could make $\beta L = \pi/2$ by choosing a metamaterial with $\mu\epsilon$ dominated by the real part with $1/f^2$ frequency dependence, then the structure would become a high- Z " $\lambda/4$ " reflecting surface for all the frequencies in the band.

However, such metamaterial does not exist.^{56,57} Nevertheless, in the future, multilayer FSS using metallic screens may be replaced by lightweight high index and very thin meta-ferrite film composite materials.⁵⁷

24.5 PROTOTYPE WIDEBAND ARRAYS

Conventional wideband arrays use discrete radiating elements that are usually costly to fabricate for low band applications, and their high profiles are problematic for airborne platforms. To overcome these drawbacks, a long slot array without discrete protruding elements was developed. Figure 24-20a shows a test array of 15×15 elements built by Raytheon for 0.4–2.0 GHz experiment. The lattice spacing of 7.6 cm (3") was chosen to support $\pm 60^\circ$ of grating lobe free scan in both E - and H -planes at the highest frequency. The total thickness of the array between the ground plane and the back plate is 8.1 cm, including a 2-cm layer of air-foam stripline transformer (50- Ω input to 188- Ω “push-pull” balun feedline). The array was only 0.1λ thick at the lowest operating frequency. Additional details are given in Lee et al.³² Another example of the long slot array is shown in Figure 24-20b, which is a compact ultra-lightweight UHF array designed for large-scale airship sensors. The UHF test array has 4×8 (32) elements (1.12 m \times 2.24 m \times 23 cm) built and tested for 150–600 MHz operation. The array is 23 cm thick, and it weighs 7 kg (2.8 kg/m²). Lossy loading material may be used to make it thinner, but this is believed to be the lightest and thinnest UHF array reported for wideband applications without gain penalty. Array patterns, gain, and cross-pol level were measured, and the results were reported in Lee et al.³⁴

Raytheon has built wide-band multifunction arrays capable of simultaneous and time interleaved radar, electronic warfare, and communications functions.⁵⁸ It has also developed a 10:1 bandwidth flared notch (tapered slot) element, operating from 1.8 to 18 GHz, on the DARPA Reconfigurable Aperture (RECAP) Program. The element provides dual orthogonal polarizations with wide scan range capability. A picture of the RECAP element is shown in Figure 24-21. To achieve decade bandwidth, the (cavity-backed) hockey-stick balun and the tapered notch element must be designed to achieve the required bandwidth separately and when cascaded while fitting within the allowed element depth and spacing. The tapered notch was approximated by a large number of slotline segments, each characterized by an

FIGURE 24-20 Wideband long slot arrays: (a) 15×15 elements for 0.4–2.0 GHz band and (b) 4×8 -element UHF array for 150–600 MHz demonstration

FIGURE 24-21 RECAP Program Dual Polarized Apertures for 1.8–18-GHz operation

S-matrix. An optimizer was used to determine the tapered notch width profile that provides the minimum element return loss over the specified bandwidth. Note that both the balun and taper separately may not perform satisfactorily at the very low frequency end, but the overall element can be optimized to perform well at the low end limit.

For low profile applications, flared dipole (bunny-ear) elements are more useful. Figure 24-22a shows a 9×9 -element test array designed for low band (1–5 GHz).^{59,60} A partial view of a 25×25 -element high band (3–14 GHz) array is shown in Figure 24-22b. In the experiment,⁶¹ the embedded element pattern was measured, and it tracks with the cosine pattern fairly well up to 60° over the band. The rise time of the impulse response is 100 picoseconds, confirming 10-GHz instantaneous bandwidth. The cross-pol components are 30 dB below at broadside and 20 dB on average up to 60° in all principal planes, a feature not enjoyed by the long tapered slot element.

The flared dipole element was also used in a small UHF antenna for FOPEN SAR application.^{62,63} As shown in Figure 24-23, it is a dual-linearly polarized array consisting of 4×4 elements in the V-pol and 3×4 elements in the H-pol. It operates over a 4:1 bandwidth (150–600 MHz), with VSWR less than 2:1 over the band. The “egg-crate” array was designed to fit in a small radome (50 cm \times 100 cm \times 100 cm). Each set of radiating elements produces a side-looking beam, shaped to cover a broad region in the elevation and azimuth plane, with the beam peak pointed in the direction of 30° depression angle from the horizon.

25.3 ADAPTIVE BEAMFORMING	25-3

25.1 INTRODUCTION

Modern *beamsteered* arrays, where the pattern is shaped according to various optimum criteria, are called smart antennas. Smart antennas have alternatively been referred to as *digital beamformed* (DBF) arrays or *adaptive* arrays (when adaptive algorithms are employed). The term “smart” implies the use of signal processing in order to shape the beam pattern according to certain conditions. Smart antennas hold the promise for improved sensing systems,¹⁻⁶ improved system capacities with mobile wireless, and improved wireless communications⁷⁻⁹ through the implementation of space division multiple access (SDMA).

Smart antenna patterns are controlled by algorithms based upon optimizing certain criteria. These criteria are typically based on maximizing the signal-to-interference ratio (SIR), minimizing the variance, minimizing the mean-square error (MSE), steering toward a signal of interest, or nulling depth against interfering signals. These criteria can be used in static fixed geometries or in dynamic tracking of moving emitters and interference.

Although there are many smart antenna algorithms, we will only review the canonical methods that include least mean squares (LMS), sample matrix inversion (SMI), recursive least squares (RLS), conjugate gradient method (CGM), constant modulus algorithm (CMA), and the least squares constant modulus algorithm (LS-CMA).

25.2 THE HISTORICAL DEVELOPMENT OF SMART ANTENNAS

The development of smart antennas began in the late 1950s. The term “adaptive array” was first coined by Van Atta¹⁰ in 1959 to describe a *self-phased* array. Self-phased arrays merely reflected all incident signals back in the direction of arrival by using phase conjugation schemes. Self-phasing has alternatively been called *retrodirection*. Self-phased arrays are instantaneously adaptive arrays since they essentially reflect the incident signal in a fashion similar to the classic corner reflector.

Phase-locked loop (PLL) systems were incorporated into arrays in the 1960s in an effort to construct better retrodirective arrays.¹¹ PLLs are still used in single beam scanning systems.¹²

Adaptive sidelobe cancellation (SLC) was first proposed by Howells^{13,14} in 1959. This technique allowed for interference nulling, thus raising the signal-to-interference ratio. The Howells SLC was the first adaptive scheme that allowed for automatic interference nulling. By maximizing the generalized signal-to-noise ratio, Applebaum developed the algorithm governing adaptive interference cancellation,^{15,16} which is now referred to as the Howells-Applebaum algorithm. At the same time, through the use of least mean squares (LMS), Widrow and others applied self-training to adaptive arrays.^{17,18} The Howells-Applebaum and Widrow algorithms are both steepest-descent/gradient-search methods that converge to the optimum Wiener solution. The convergence rate of these methods is dependent upon the eigenvalue spread¹⁹ such that larger spreads require longer convergence times. The convergence time constant is given by Monzingo and Miller²⁰:

$$\tau_i = \frac{1}{2\mu\lambda_i} \quad (25-1)$$

where

μ = gradient step size

λ_i = i th eigenvalue

The eigenvalues are derived from the covariance matrix of array voltages. The largest eigenvalues correspond to the strongest signals.

Since the convergence of the SLC algorithm is slow for large eigenvalue spreads, Reed, Mallett, and Brennen²¹ developed the direct sample matrix inversion (SMI) technique in 1974. Another means of improving the eigenvalue limited convergence rate is through the use of conjugate gradient methods. Most notably, Powell's method²² has been applied to steepest descent problems.

In many modern communication systems, the signals of interest are phase or frequency modulated. Thus the signal amplitude, or modulus, should be constant in the absence of multipath and fading. As a consequence of the constant modulus property, many popular blind adaptive algorithms have been developed. These include the Godard constant modulus algorithm (CMA) proposed in 1980²³ and the least squares constant modulus algorithm (LS-CMA) proposed by Agee²⁴ in 1986.

A complementary advance in smart antennas came with the application of spectral estimation methods to array processing. In 1969 Capon²⁵ used a maximum likelihood (ML) method to solve for the minimum variance distortionless response (MVDR) of an array. In 1972 Burg applied the maximum entropy method to spectral estimation, and his technique was soon adapted to array signal processing.^{26,27} In 1973 Pisarenko²⁸ developed the harmonic decomposition technique based upon minimizing the mean-squared error under the constraint that the norm of the weight vector be equal to unity. The minimum-norm (min-norm) method was developed by Reddi²⁹ in 1979 and improved by Kumaresan and Tufts³⁰ in 1983. The min-norm algorithm optimizes the weight vector by solving the optimization problem where the weight vector is orthogonal to the signal eigenvector subspace. The now famous MUSIC algorithm developed by Schmidt³¹ in 1986 is a spectral estimation algorithm that exploits the orthogonality of the noise subspace of the array covariance matrix. The ESPRIT technique was first proposed by Roy and Kailath³² in 1989. The goal of ESPRIT is to exploit the rotational invariance in the signal subspace that is created by two arrays with a translational invariance structure.

Many adaptive methods allow the user to achieve higher resolutions than that permitted by the beamwidth of the array. The price of increased resolution comes at the cost of greater computational intensity.

25.3 ADAPTIVE BEAMFORMING

The fixed beamforming approaches assume a stationary geometry with a fixed emitter angle of arrival (AOA). If the signal AOAs do not change with time, the optimum array weights do not need to be updated after they are initially found. However, if the desired arrival angles change with time, it is necessary to devise an optimization scheme that operates "on-the-fly" to continually recalculate the optimum array weights. The receiver signal processing algorithm must allow for a stepwise update of weights in order to adapt to the continuously changing electromagnetic environment. The adaptation process must satisfy a specified optimization criterion. Several popular optimization techniques include least mean squares (LMS), sample matrix inversion (SMI), recursive least squares (RLS), the conjugate gradient method (CGM), and the constant modulus algorithm (CMA). Each of these techniques is described in the sections that follow.

Least Mean Squares

The least mean squares algorithm is a gradient-based approach. Monzingo and Miller²⁰ give an excellent fundamental treatment of this approach. Gradient-based algorithms assume an

established quadratic performance surface. The performance surface (or cost function), $C(\bar{w})$, is in the shape of an elliptic paraboloid having one minimum. One of the best ways to establish the minimum is through the use of a gradient method by minimizing the cost function. Consider the adaptive array shown in Figure 25-1.

The M -element array has M weights that can be adjusted to modify the beam pattern. It is generally assumed that there is one arriving signal of interest $s(k)$ with N arriving interferers. One time sample is represented by k . The m th array element has an output, $x_m(k)$, which consists of the desired signal, interfering signals, and noise. Often a desired signal $d(k)$ is employed that is representative of the signal $s(k)$ and that can be used to “train” the array weights in order to enhance the signal $s(k)$ at the array output. An error signal, $\varepsilon(k)$, is generally calculated as the difference between the array output, $y(k)$, and the desired signal, $d(k)$. The error can be minimized by minimizing the mean squared error (MSE).

The error, as shown in Figure 25-1, is given as

$$\varepsilon(k) = d(k) - \bar{w}^H(k)\bar{x}(k) \quad (25-2)$$

The squared error is given as

$$|\varepsilon(k)|^2 = |d(k) - \bar{w}^H(k)\bar{x}(k)|^2 \quad (25-3)$$

Through some simple algebra, it can be shown that the mean-square error is given by

$$|\varepsilon(k)|^2 = |d(k)|^2 - 2d(k)\bar{w}^H\bar{x}(k) + \bar{w}^H\bar{x}(k)\bar{x}^H(k)\bar{w} \quad (25-4)$$

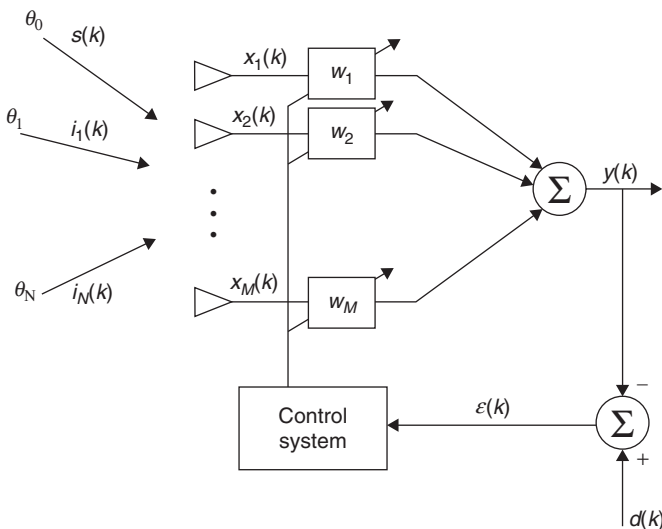

FIGURE 25-1 Typical adaptive array block diagram

For the purposes of simplification, we will suppress the time dependence notation k . Taking the expected value of both sides and simplifying the expression, we get

$$E[|\varepsilon|^2] = E[|d|^2] - 2\bar{w}^H \bar{r} + \bar{w}^H \bar{R}_{xx} \bar{w} \quad (25-5)$$

where the following vector and matrix covariances are defined:

$$\bar{r} = E[d^* \cdot \bar{x}] = E[d^* \cdot (\bar{x}_s + \bar{x}_i + \bar{n})] \quad (25-6)$$

$$\bar{R}_{xx} = E[\bar{x}\bar{x}^H] = \bar{R}_{ss} + \bar{R}_{uu} \quad (25-7)$$

$$\bar{R}_{ss} = E[\bar{x}_s \bar{x}_s^H] \quad (25-8)$$

$$\bar{R}_{uu} = \bar{R}_{ii} + \bar{R}_{nn} \quad (25-9)$$

The expression in Eq. 25-5 is a quadratic function of the weight vector \bar{w} . This function is sometimes called the “performance surface” or “cost function” and forms a quadratic surface in M -dimensional space. Since the optimum weights provide the minimum MSE, the extremum is the minimum for this function. A trivial example of a performance surface is given for a two-element array that produces a two-dimensional surface as depicted in Figure 25-2. As the desired angle-of-arrival changes with time, the quadratic surface minimum changes with time in the weight plane.

The cost function of Eq. 25-5 can be rewritten as

$$C(\bar{w}) = D - 2\bar{w}^H \bar{r} + \bar{w}^H \bar{R}_{xx} \bar{w} \quad (25-10)$$

where

$$D = E[|d|^2]$$

The performance surface is determined from the gradient of Eq. 25-10 with respect to the weight vector. Thus

$$\nabla_{\bar{w}}(C(\bar{w})) = 2\bar{R}_{xx} \bar{w} - 2\bar{r} \quad (25-11)$$

The minimum occurs when the gradient is zero. With the left side of Eq. 25-11 set to zero, the optimum Wiener solution for array weights is given by

$$\bar{w}_{\text{opt}} = \bar{R}_{xx}^{-1} \bar{r} \quad (25-12)$$

FIGURE 25-2 Quadratic surface for MSE

The Wiener solution of Eq. 25-12 is based on assuming knowledge of all signal statistics. In general, we do not know the signal statistics and must resort to estimating both the array covariance matrix (\hat{R}_{xx}) and the signal covariance vector (\hat{r}) at an instant in time or over a block of time samples. The instantaneous estimates of array covariance and (ideal) signal covariance are given as

$$\hat{R}_{xx}(k) \approx \bar{x}(k)\bar{x}^H(k) \quad (25-13)$$

and

$$\hat{r}(k) \approx d^*(k)\bar{x}(k) \quad (25-14)$$

We can employ an iterative technique called the *method of steepest descent* to approximate the gradient of the cost function. The method of steepest descent can be approximated in terms of the weights using the least mean squares (LMS) method advocated by Widrow et al.^{17,18} The direction of steepest descent is in the opposite direction of the gradient vector and, in an iterative approximation, is given as

$$\bar{w}(k+1) = \bar{w}(k) - \frac{1}{2} \mu \nabla_{\bar{w}}(C(\bar{w}(k))) \quad (25-15)$$

where

μ = step-size parameter

$\nabla_{\bar{w}}$ = gradient of the performance surface

If we substitute the instantaneous covariance approximations of Eqs. 25-13 and 25-14 and the performance surface gradient from Eq. 25-11, the LMS solution can now be written as

$$\begin{aligned} \bar{w}(k+1) &= \bar{w}(k) - \mu [\hat{R}_{xx} \bar{w} - \hat{r}] \\ &= \bar{w}(k) + \mu e^*(k) \bar{x}(k) \end{aligned} \quad (25-16)$$

where

$$e(k) = d(k) - \bar{w}^H(k) \bar{x}(k) = \text{error signal}$$

The convergence of the LMS algorithm is directly proportional to the step-size parameter μ . If the step-size is too small, the convergence is slow (overdamped case). If the convergence is slower than the changing angles of arrival, it is possible that the adaptive array cannot acquire the signal of interest and therefore cannot track the changing signal. If the step-size is too large, the LMS algorithm will overshoot the optimum weights of interest (underdamped case). Under this condition, convergence is too fast, and the weights will oscillate about the optimum weights, but will not accurately track the desired solution. It is therefore imperative to choose a step-size in a range that ensures optimal convergence. Stability of convergence is provided when the following condition is met:²⁰

$$0 \leq \mu \leq \frac{1}{2\lambda_{\max}} \quad (25-17)$$

where

$$\lambda_{\max} = \text{the largest eigenvalue of } \hat{R}_{xx}$$

Since the covariance matrix is positive definite, all eigenvalues are positive. If all the interfering signals are noise and there is only one signal of interest, we can approximate the condition in Eq. 25-17 as

$$0 \leq \mu \leq \frac{1}{2 \text{ trace}[\hat{R}_{xx}]} \quad (25-18)$$

As an example of the LMS routine, let us model an $M = 8$ element array with uniform element spacing of $\lambda/2$. Assume the desired signal is arriving at the angle $\theta_0 = 30^\circ$ and an interferer arrives at the angle $\theta_1 = -60^\circ$. Allowing the step size to be $\mu = .02$, Figure 25-3

FIGURE 25-3 Magnitude of array weights

FIGURE 25-4 Acquisition and tracking of desired signal

shows the resulting magnitude of antenna element weights over 100 iterations. Figure 25-4 shows how the array output acquires and tracks the desired signal over 100 iterations. Figure 25-5 shows how the resulting mean square error converges to nearly zero after 25 iterations. Figure 25-6 shows the final weighted array pattern, which as expected, has a peak at the desired direction of 30° and a null at the interfering direction of -60° .

FIGURE 25-5 Mean square error

FIGURE 25-6 Weighted LMS array

Sample Matrix Inversion

One of the drawbacks of the LMS adaptive scheme is that the algorithm must go through many iterations before satisfactory convergence is achieved. If the signal characteristics are rapidly changing, the LMS adaptive algorithm may not allow tracking of the desired signal in a satisfactory manner. The rate of convergence of the weights is dictated by the eigenvalue spread of the array covariance matrix, as indicated by Eq. 25-1. In the previous example, the LMS algorithm did not converge until after 25 iterations. One possible approach to circumventing the relatively slow convergence of the LMS scheme is by use of sample matrix inversion (SMI).^{7,26,33} This method is also known as direct matrix inversion (DMI).²⁰ The “sample matrix” is a time average estimate of the array covariance matrix using K time samples. If the random process is ergodic, then the time average estimate of covariance matrix will rapidly approach the actual estimate of the covariance matrix.

Recalling the earlier discussion of the minimum mean square error (MSE), the optimum array weights are given by the optimum Wiener solution as

$$\bar{\mathbf{w}}_{\text{opt}} = \bar{\mathbf{R}}_{xx}^{-1} \bar{\mathbf{r}} \quad (25-19)$$

where

$$\bar{\mathbf{r}} = E[d^* \cdot \bar{\mathbf{x}}]$$

$$\bar{\mathbf{R}}_{xx} = E[\bar{\mathbf{x}} \bar{\mathbf{x}}^H]$$

Under conditions of covariance ergodicity, we can estimate the covariance matrix by calculating the time average of a block of data such that

$$\hat{R}_{xx} = \frac{1}{K} \sum_{k=1}^K \bar{x}(k) \bar{x}^H(k) \quad (25-20)$$

where

K = number of data samples in a block

In similar fashion, the covariance vector \bar{r} can be estimated by the time average

$$\hat{r} = \frac{1}{K} \sum_{k=1}^K d^*(k) \bar{x}(k) \quad (25-21)$$
